Thanks for explaining that, John. I am unfamiliar with the conventions
of LaTex, obviously (I get my information from books that are generally
older than I am, and I'm not young). I don't have any problem with
Gauss' law being used in a non-static context. It applies, regardless.
That's as far as I go in agreeing with Art, though, since I can't
understand the rest of his theory, at all (but might if I could turn
off the left side of my brain - maybe).

I dont intend to make anything that will crank up, tilt over is a consideration as I once saw a magazine article with design parameters and understand the person who wrote the article also may have written software.

I have set a light pole before. I got theinfo from the local power company on how much of it should be buried and a friend that has a wrcker helped me put it in he ground. Since the bottom end is considerably heavier than the top the center of gravity is much lower than the actual center. this makes things a lot easier than it may appear. Hardest part by far was digging the hole.

Much has been said in this thread concerning whether reflected power does or does not enter the power
amplifier and cause heating of the plate. In describing below the experimental procedure that I have performed
many times in my RF Lab, I am offering proof here that such heating does not occur.

The following material from Chapter 19A of Reflections 3 is presented to show why reflected power
does not enter the amplifier and cause heating of the tube plate.

"Weï¿½ll now examine the experimental data that resulted from measurements performed subsequent to those reported in Chapter 19, new data that provides additional evidence that a
conjugate match exists at the output terminals of an RF power amplifier when all of its available power is delivered into its load, however complex the load impedance. According to
the definition of the conjugate match as explained earlier, if this condition prevails

there is a
conjugate match. In addition, the data presented below also provides further evidence that the
output source resistance of the RF amplifier is non-dissipative. CONSEQUENTLY, THIS EVIDENCE
PROVES THAT REFLECTED POWER DOES NOT CAUSE HEATING OF THE PLATE. The following steps describe
the experimental procedure I employed and the results obtained:

1. Using a Kenwood TS-830S transceiver as the RF source, the tuning and loading of the pi-network are adjusted to deliver all the available power into a 50 + j0-ohm load with the grid
drive adjusted to deliver the maximum of 100 watts at 4 MHz, thus establishing the area of the RF power window at the input of the pi-network, resistance RLP at the plate, and the slope of the load line. The output source resistance of the amplifier in this condition will
later be shown to be 50 ohms. In this condition the DC plate voltage is 800 v and plate current is 260 ma. DC input power is therefore 800 v x 0.26 a = 208 w. Readings on the Bird 43 wattmeter indicate 100 watts forward and zero watts reflected. (100 watts is the maximum RF output power available at this drive level.) From here on the grid drive is left undisturbed, and the pi-network controls are left undisturbed until Step 10.

2. The amplifier is now powered down and the load resistance RL is measured across the input
terminals of the resonant pi-network tank circuit (from plate to ground) with an HP-4815 Vector Impedance Meter. The resistance is found to be approximately 1400 ohms. Because the amplifier was adjusted to deliver the maximum available power of 100 watts prior to the resistance measurement, the average of the dynamic resistance RLP looking into the plate (upstream from the network terminals) is also approximately 1400 ohms. Accordingly, a non-reactive 1400-ohm resistor is now connected across the input terminals of the pi-network
tank circuit and output source resistance Ros is measured looking rearward into the output terminals of the network. Resistance Ros was found to be 50 ohms.

3. Three 50-ohm dummy loads (a 1500w Bird and two Heathkit Cantennas) are now connected in parallel to provide a purely resistive load of 16.67 ohms, and used to terminate a coax of
13.5ï¿½ length at 4 MHz.

4. The impedance ZIN appearing at the input of the 13.5ï¿½ length of coax at 4 MHz terminated
by the 16.67-ohm resistor of Step 3 is measured with the Vector Impedance Meter, and found to be 20 ohms at +26ï¿½. Converting from polar to rectangular notation, Zin = 17.98 + j8.77 ohms. (Zin = Zload from the earlier paragraphs.) This impedance is used in Steps 5 and 6 to provide the alternate load impedance in the load-variation method for determining the complex output impedance of the amplifier, and for proving that the conjugate match exists.

5. With respect to 50 ohms, Zin from Step 4 yields a 2.88:1 mismatch and a voltage reflection
coefficient (rho) 0.484. Therefore, power reflection coefficient (rho squared) 0.235, transmission
coefficient (1 - 0.235) = 0.766, and forward power increase factor 1/(1- 0.235) = 1/0.766 =

1.306.

6. Leaving pi-network and drive level adjustments undisturbed, the 50-ohm load is now replaced with the coax terminated with the 16.67-ohm load from Step 4, thus changing the load impedance from 50 ohms to 17.98 + j8.77 ohms, the input impedance Zin of the coax.

7. Due to the 2.88:1 mismatch at the load, neglecting network losses and the small change in
plate current resulting from the mismatch, approximately the same mismatch appears between RLP and ZL at the input of the pi-network. Consequently, the change in load impedance changed the network input resistance RL from 1400 ohms to complex ZL = 800 - j1000 ohms, measured with the Vector Impedance Meter using the method described in Step 2. To verify the impedance measurement of ZL the phase delay of the network was measured using an HP-8405 Vector Voltmeter and found to be 127ï¿½. Using this value of phase delay the input impedance ZL was calculated using two different methods; one yielding 792 - j1003 ohms, the other yielding 794.6 - j961.3 ohms, thus verifying the accuracy of the measurement. However, because grid voltage Ec, grid drive Eg, and plate voltage Eb are left unchanged, the average dynamic resistance RLP at the plate has remained at approximately 1400 ohms, leaving a mismatch between RLP and ZL at the input of the pi-network.
As stated above, this value of ZL yields the substantially the same mismatch to plate resistance
RLP as that between the output impedance of the pi-network and the 17.98 + j8.77-ohm load, i.e.,
2.88:1. This mismatch at the network input results in less power delivered into the network,
and thus to the load, a decrease in the area of the RF window at the network input, and a change in the slope of the loadline. (It must be remembered that the input and output mismatches contribute only to mismatch loss, which does not result in power delivered and then lost somewhere in dissipation. As we will see in Step 8, the mismatch at the input of the pi-network results only in a reduced delivery of source power proportional to the degree of mismatch.)

8. Readings on a Bird 43 power meter now indicate 95w forward and 20w reflected, meaning only 75 watts are now delivered by the source and absorbed in the mismatched load. The 20w reflected power remains in the coax, and adds to the 75 watts delivered by the source to
establish the total forward power of 95w.

9. We now compare the measured power delivered with the calculated power, using the power transmission coefficient, (1 - 0.235). The calculated power delivered is: 100w x (1 - 0.235) = 76.6w,
compared to the 75w indicated by the Bird wattmeter. However, because the new load impedance is less than the original 50 ohms, and also reactive, the amplifier is now overloaded and the pi-network is detuned from resonance. Consequently, the plate current has increased from 260 to 290 ma, plate voltage has dropped to 760 v, and DC input power has increased from 208 w to 220.4 w.

10. With the 17.98 + j8.77-ohm load still connected, the pi-network loading and tuning are now re-adjusted to again deliver all available power with drive level setting still left undisturbed. The readjustment of the plate tuning capacitor has increased the capacitive reactance in the pi-network by -8.77 ohms, canceling the +8.77 ohms of inductive reactance in the load, returning the system to resonance. The readjustment of the loading control

capacitor has decreased the output capacitive reactance, thus reducing the output resistance
from 50 to 17.98 ohms. Thus the network readjustments have decreased the output impedance from 50 + j0 to 17.98 - j 8.77 ohms, the conjugate of the load impedance, 17.98 + j8.77 ohms. The readjustments have also returned the network input impedance ZL to 1400 + j0 ohms (again equal to RLP), have returned the original area of the RF window at the network input, and have returned the slope of the loadline to its original value. For verification of the 1400-ohm network input resistance after the readjustment, ZL was again measured using the method described in Step 2, and found it to have returned to 1400 + j0 ohms.

11. Bird 43 power meter readings following the readjustment procedure now indicate 130w forward and 29.5w reflected, indicating 100.5w delivered to the mismatched load.

12. For comparison, the calculated power values are: Forward power = 100 x 1.306 = 130.6w, reflected power = 30.6w, and delivered power = 130.6w - 30.6w = 100w showing substantial agreement with the measured values. (1.306 is the forward power increase factor determined in Step 5.) Plate current has returned to its original value, 260 ma, and likewise,
plate voltage has also returned to the original value, 800 v. Consequently, the DC input power has also returned to its original value, 208 w.

13. It is thus evident that the amplifier has returned to delivering the original power, 100 watts
into the previously mismatched complex-impedance load, now conjugately matched, the same as when it was delivering 100 watts into the 50-ohm non-reactive load. But the reflected power, 30.6 watts, remains in the coax, adding to the 100 watts delivered by the amplifier to establish the 130.6 watts of forward power, proving that it does not enter the amplifier to dissipate and heat the network or the tube.

It must be kept in mind that impedance Zin appearing at the input of the 13ï¿½ line connecting
the 16.7-ohm termination to the output of the amplifier is the result of reflected waves of both
voltage and current, and thus reflected power is returning to the input of the line, and becomes
incident on the output of the amplifier.
The significance of these measurement data is that for the amplifier to deliver all of its available power (100w) into the mismatched load impedance Zin = 17.98 + j8.77 ohms, the readjustment of the tuning and loading of the pi-network simply changed the output impedance of the network from 50 + j0 ohms to 17.98 - j8.77 ohms, the conjugate of the load impedance, thus matching the output impedance of the network to the input impedance of the coax. Consequently, there IS a conjugate match between the output of the transceiver and its complex load. QED. The readjustments of the pi-network simply changed its impedance transformation ratio from 50:1400 to (17.98 - j8.77):1400, returning the input resistance RL of the pi-network to 1400 ohms, the value of RLP. Thus the plates of the amplifier
tubes are unaware of the change in external load impedance.

14. Weï¿½ll now make an additional indirect measurement of Ros that proves the conjugate match statement above is true. Leaving the pi-network adjustments undisturbed from the conditions in Step 10, with the amplifier powered down we again connect a 1400-ohm non-

reactive resistor across the input terminals of the pi-network tank circuit and measure the output source
impedance Zos looking rearward into the output terminals of the network. The impedance was found to be Zos = 18 - j8 ohms.

From a practical viewpoint, measured impedance Zos = 18 - j8 ohms is the conjugate of load impedance Zload = 17.98 + j8.77, proving that the amplifier is conjugately matched to the load, and also proving the validity of the indirect method in determining that the source
impedance of the amplifier is the conjugate of the load impedance when all available power is
being delivered to the load.
Thus the data obtained in performing Steps 1 through 14 above proves the following four conditions to be true:

No reflected power incident on the output of the amplifier is absorbed or dissipated in the amplifier, because:

1. The total DC input power is the same whether the amplifier is loaded to match the resistive
Z0 load of 50 + j0 ohms, with no reflected power, or to match the complex load of 17.98 - j8.77 ohms with 30.6 watts of reflected power, while 100 w is delivered to either the Z0 load or
the re-matched complex load.

2. All the 100 watts of power delivered by the transmitter is absorbed in both the Z0 load and
the re-matched complex load cases, with the same DC input power in both cases.

3. All the 30 watts of reflected power has been shown to add to the source power, establishing
the total 130 watts of forward power in the case involving the re-matched complex load.

4. All the reflected power is added to the source power by re-reflection from the non-dissipative output source resistance Ros of the amplifier. Had the output source resistance of
the amplifier been dissipative the reflected power would have been dissipated there to heat,
instead of being re-reflected back into the line and adding to the source power. In addition, the
Bird 43 power meter would have indicated 75 watts of forward power, not 95. This proves that
reflected power incident on the output of the amplifier does not cause heating of the tube.

It should also be noted, an accepted alternative to the load-variation method for measuring the output impedance of a source of RF power is the indirect method demonstrated above. As performed during the measurements described above, the procedure for this method is to first
make the necessary loading adjustments of the output network to ensure that all of the available power is being delivered to the load. Next, the input impedance of the load is measured. It then follows that, as proven above, the source impedance is the conjugate of the

input impedance measured at the input of the load, because when all available power is being
delivered to the load, this condition conforms to the Conjugate Matching and the Maximum Power-transfer Theorems.
Additionally, I previously performed this same measurement procedure using a HeathKit HW-100 transceiver, using several different lengths of coax between the 16.7-ohm load and the output of the transceiver in each of several measurements. The different lengths of coax
provided different complex load impedances for the transceiver during each measurement. The
same performance as described above resulted with each different load impedance, providing further evidence that a conjugate match exists when the amplifier is delivering all of its available power into its load. These results also prove that the single test with the Kenwood
transceiver is not simply a coincidence.

More recent experimental evidence has been presented since that of Chapter 19, adding further proof that a conjugate match can exist when the source is an RF power amplifier, and
that the output source resistance of the amplifier is non-dissipative. It was also shown that
the average dynamic resistance RLP looking toward the plate from the network input equals resistance RL appearing at the input of the pi-network when a conjugate match is obtained, while contrary to Brueneï¿½s claim, there is no requirement that RL = RS to obtain a conjugate match,
thus proving Brueneï¿½s definition of the conjugate match appearing in his November 1991 QST
article 142 invalid.

Hi Paul,

About your 868 MHz project (probably european [ETSI] SRD application).

The datasheet gives impedance requirement that should function when connected directly to 50 Ohms. I saw (little bit surprised) the datasheet doesn't give a reference design.

If the design is to be terminated with 50 Ohms, and you run a coaxial cable from bulkhead to PCB (both sides bread of cable connected), it should be OK (irrespective of cable length). I assume that the antenna that you are using is a 50 Ohms antenna (a quarter wave?). The antenna will us the metal casing as ground plane avoiding RF currents inside the housing.

Sometimes, circuits may become instable (out of band or just out of band) when changing the cable length. You may check this by adding a 3 or 6 dB attenuation. Normally spoken, adding 6 dB will reduce the range with about a factor 2 (assuming free space, not close to ground).

Other things can be interference on the IF (directly onto the chip) from a switching regulator or digital HW. Is it possible that you are close to other applications (for example 2W UHF RFID, or UHF broadcast stations). You should see that on the analog I&Q outputs, If you move with the antenna, with no transmitter present, the output noise should not change (so not become more or becoming less).

When this a commercial application, and have some budget, you may hire a specialist. Many of the single chip TRX are difficult to get in line with EN300220, though the datasheet does mention compliance.

Best Regards,

Wim
PA3DJS.

> is offset from the main image as related to the round-trip propagation
> time of the transmission line.

Richard, read this carefully, I do NOT disagree with what you have said in the paragraph above.

For a ghost to be visible to viewers getting signal off air, there is more at play that a 5% reflection from a far end mismatch, the reflected wave is heading towards the transmitter, and needed to encounter another at least another reflection point with sufficiently high reflection coefficient that a sufficiently large, time delayed copy of the original modulated wave reaches the load (even if in turn part is reflected again).

This second point of reflection could be a transmission line discontinuity, but it is most likely that it was that the tx end of the transmission line was not matched, that is that the tranmitter did not terminate the line with a near perfect match.

It leaves the questions "are transmitters matched to Zo in real life, is matching an unavoidable consequence of optimising power output?".

For avoidance of doubt, the discussion in this post is about the transient behaviour of the tranmission line and waves, it is relevant to long transmission lines with analogue TV modulation, but that doesn't mean it is necessarily important to other applications.

I've discussed my method before in this group. DAGS for "wes cleaning
aluminum" for the writeup.

Unfortunately, in my location the meth labs were using lots of lye so
we can't buy it at Ace Hardware anymore.

> matching an unavoidable consequence of optimising power output?"

Field experience in my tenure with RCA Broadcast when measuring and minimizing the "ghosting" propensities of commercial analog broadcast TV transmission systems showed/shows that a measured 5% or greater voltage reflection from the transmit antenna/input elbow complex, when sufficiently displaced in time from the main image, will result in an objectionable ghost image seen on an off-air TV set tuned to that station.

That would not be true if such a nominal 5% far-end reflection from the antenna system essentially was absorbed by the TV transmitter (whether or not that turned the tube PA plates red, or caused the failure or other compromise of a solid-state PA).

Maximizing the output power and efficiency of a broadcast r-f amplifier dictates that its effective output Z must be greatly different than the load Z it is expected to drive. In the case of broadcast transmitters, that source impedance is low (a few ohms), compared to the typical 50 or 75 ohm Zo of the load it is driving.

And this it the reason that much of the voltage reflected from an antenna/far-end mismatch returns from the tx back to the antenna to be radiated, and so to produce the TV ghost image seen under those conditions.

An equivalent effect is a reality in FM broadcasting, where a poor Z match of the antenna system across the FM channel bandwidth produces synchronous AM, and adds to stereo and SCA crosstalk.

On the contrary, I have presented at least three references as proof.
If I remember correctly, it was Ramo, Whinnery, Hecht, and Balanis.
You, OTOH, have presented none.

> My contention is that this distinction is merely a matter of
> mathematical preference. When standing waves occur, there is absolutely
> no physical difference between the standing wave and its traveling wave
> constituents.

Obviously false as proven by the different equations for the two types
of waves. We laid that one to rest long ago. In fact, it was you who
pointed out that standing wave phase is completely different from
traveling wave phase and cannot be used to measure phase shift through
a coil. If I remember correctly, it was the difference between
cos(x*wt) and cos(x)*cos(wt), i.e. *very* different.

No, it is virtually identical to your argument. Saying it is "totally
irrevelent" doesn't change anything. You are arguing that net energy
transfer is primary and the underlying energy components are
irrelevant if nonexistant.

I wrote:
"Obviously 100W is dissipated inthe transmitter and efficiency is 50%."

This is a Class A amplifier limit but not for other classes of amplifiers. Terman tells us on page 450 of his 1955 opus:
"The high efficiency of the Class C amplifier is a result of the fact that plate current is not allowed to flow except when the instantaneous voltage drop across the tube is low; i.e., Eb supplies energy to the amplifier only when the largest portion of this energy will be absorbed by the tuned circuit.

"Transmission Lines, Antennas, and Wave Guides" by King, Mimno, and Wing is an excellent reference, and like Terman, the authors agree with Walter Maxwell. On page 43 is found:
"Principal of Conjugates in Impedance Matching - If a dissipationless network is inserted between a constant-voltage generator of impedance Zg and a load of impedance ZR such that maximum power is delivered to the load, at every pair of terminals the impedance looking in opposite directions are conjugates of each other."

The real world is full of imperfections which by no means preclude practical work.

Best regards, Richard Harrison, KB5WZI

For whatever reason, ghosting of this sort proves that the reflected
energy
makes a round trip from the load to the source and back. The ghosting
delay is exactly what a speed-of-light EM traveling wave would
experience.
In fact, multiple ghosting is caused by multiple reflections.

This is not correct. It has nothing to do with the output impedance of the drivers. Even a 50 ohm Thevenin source will reflect _all_ the power back to the load as long as it is 'matched'.

Here is how to prove this to your self. Take a transmitter and tune it up into a dummy load. The effective output impedance is now 50 ohms. Now plug that transmitter into a trans-match that drives some coax to a long wire. When the match is tuned there will be no energy flowing from the match back to the transmitter. All the energy reflected from the long wire gets reflected back from the match even if a 50 ohm source is used.

Best, Dan.

IMHO: Take a look at the steppir verticals
http://www.steppir.com/
No traps, coils, capacitors or linear loading of any kind.

Full continuous coverage, including WARC bands-without compromise! 2000 W
PEP Rating.

Used on several DXpeditions with rave reviews

That's the one I would buy if I could put in a good ground radial system -
but I have no room for radials. So don't own one, a friend does and for what
is worth he claims it is the best vertical he has ever owned over 30 years
including, Butternut, Cushcraft, Hustler, Hy-Gain, etc

But the steppir's are pricey $595 and $695

Good luck

CL

Oh no, now we'll probably see a tremendous price increase in lye and
it'll only be available on the black market ... gawd, if they only
expended part of the energy they do in the anti-drug campaign towards
something useful how lucky we would all be.

It may be cold hearted, but if someone insists on killing themselves
with drugs--more power to 'em! Better they kill themselves than someone
else as they hold up, rob, etc. normal citizens.

Calcium carbonate (Na2CO3), aka "washing soda", is sold at paint stores as "TSP substitute". It's not as alkaline as lye (pH over 13), but with a pH of 11.5 for a few percent solution it's still pretty darn alkaline. Would it work in place of lye?

Gene, how can you insist that standing waves are just
like traveling waves when their equations are so
different - different enough to make them virtually
opposites. The phase of a traveling wave varies with
distance - the phase of a standing wave doesn't. The
amplitude of a standing wave varies with distance -
the amplitude of a traveling wave doesn't (in a loss-
less transmission line). I can't think of a way that
those two types of waves are alike except for frequency.

I went to the Force 12 website and clicked on the "Flagpole antennas"
link http://force12inc.com/F12-flagpole-ants-003.htm.

I read the "New 40 Meter Coil" portion of the page with interest --
sounded too good to be true. A moment's use of the calculator showed
that the VSWR figures and the quoted feed point impedances were very
inconsistent -- orders of magnitude wrong. The claimed SWR of 16 for the
unloaded antenna worked out really to be about 850 -- close enough to
infinity for me!

If that's what the "useful A.R.R.L. TLW software" actually indicates,
then the League should withdraw the software. But somehow I suspect that
the software (which I do not have) doesn't predict what the web page
says it does.

I leave it to someone with a copy of EZNEC to see if an 1/8 wave monople
on 40 metres made out of 2 inch diameter tubing really has an input
impedance of about 5 - j460. That part, at least, sounds reasonable to me

David, ex-W8EZE, who hasn't forgotten the formulas for SWR

When a field is traveling at/near the speed of light it has mass(acts as a particle) slower and it is a wave. EM lives on the hairy edge of both worlds. vAt least thats what my Phd girlfriend told me once. Who knows though, she was pretty weird.

Your calc is about right (assuming Zo=50+j0).

TLW suffers from some of the same issues as tables in the ARRL handbooks,
but I haven't run Force12's numbers on TLW, I will use my own calculator.

>

> reasonable to me

David, I ran an analysis of a 10m "flagpole" as a multiband antenna, and
the feedpoint impedance is around the 5-j460 if you ignore resistive loss
in the ground system. Force12 might not want to include such in the
analysis as it drives much lower efficiency.

If they did achieve a coil of 10uH with Q=600, the additional R is ~0.7
ohms (about 0.6dB loss in the stated scenario), so their new 6-j22 looks
a reasonable development(apart from the fact it also ignores ground

resistance), and I make the VSWR(50) to be 10 rather than their stated 6.

At the end of the day, the VSWR is not of itself the issue, the issue is what is the line loss and load impedance presented to the ATU, then the expected tuner loss.

Their estimate of 2dB line loss for 100' is probably realistic, I make the loss on 100' of RG213 at 7MHz with load 6-j22 to be 2dB (try it yourself at http://www.vk1od.net/tl/tllc.php), and the load seen by the ATU is a manageable 8+j3.0. The Z into the line is highly dependent on the line length, but since Force12 give it, lets look at likely tuner efficiency. Using W9CF's tuner applet with default configuration, ATU loss might be around 0.7dB.

This whole scenario predicts an antenna that might be quite acceptable to people with space or covenant issues, 3.3dB of total loss.

But...

What if ground resistance was 10 ohms, efficiency of the antenna and loading coil would be 5/(10+5+0.7) or 32% (5dB loss). That will help the line loss though, now with a feed Z of 15.7-j22, loss in the same line is 1dB and input Z is 16+j2. ATU loss might be more like 0.4dB. Total loss is 5+1+0.4 or 6.4dB.

Although there analysis ignores ground resistance, possibly so as to hide the efficiency of the loaded radiator, the real situation might only be 3dB worse than they intimate.

Of course, if the coil wasn't as good as they state, the picture is a little poorer. Similarly, achieving a low ground resistance isn't easy and the story could be much worse.

Do they have credibility? Perhaps they should have stuck to the QSL card count method as the quantitative support for the design!

The idea of a flagpole sings when an automatic ATU is placed at its base, but that doesn't solve the efficiency issue that exists with any Marconi with low radiation resistance. I wrote an article exploring an unloaded vertical as a multiband antenna, it is at http://www.vk1od.net/multibandunloadedvertical/index.htm and may be of interest.

Ah, but you calculated the VSWR at the load end. They calculated the much
lower VSWR at the source end of the line.

If you were Force12, you probably wouldn't want to publicise the extreme
VSWR that users of the standard flagpole experience in this scenario.

And probably the same 145,000 years ago, while 120,000
years ago it was hotter than it is today. Every time
in the past 400K yearswhen it got approximately as hot
as it is today, an ice age "immediately" followed in
cycles of between 80K and 120K years. Just the other
day, Congress had to cancel their Global Warming
meeting because of snow. :-)

"Dan Bloomquist" wrote
> This is not correct. It has nothing to do with the output impedance of the
> drivers. Even a 50 ohm Thevenin source will reflect _all_ the power back
> to the load as long as it is 'matched'.

Following is a quotation from a paper titled "A Study of RF Intermodulation Between FM Broadcast Transmitters Sharing Filterplexed or Co-Located Antenna Systems," by G. N. Mendenhall, P.E., who then was the VP of Engineering for Broadcast Electronics, Inc, and now is VP of Product Engineering for Harris Corporation, Broadcast Division. Broadcast Electronics and Harris manufacture a full range of high power broadcast transmitters. Mendenhall is highly regarded in the broadcast industry.

In the context of the quote, the "interfering signal" means a signal coupled into the transmitter PA output circuits that was generated external to that transmitter. But the interfering signal also could be a reflection of the output signal of that transmitter from a mismatched load. Therefore the information in the quote addresses the subject of these posts.

QUOTE
"Output Return Loss" is a measure of the amount.of interfering signal that is coupled into the output circuit versus the amount that is reflected back from
the output circuit without interacting with the nonlinear device.

To understand this concept more clearly, we must remember that although the output circuit of the transmitter is designed to work into a fifty ohm load, the
output source impedance of the transmitter is not fifty ohms. If the source impedance were equal to the fifty ohm transmission line impedance, half of the transmitter's output power would be dissipated in its internal output source impedance.

The transmitter's output source impedance must be low compared to the load impedance in order to achieve good efficiency. The transmitter therefore looks
like a voltage source driving a fifty ohm resistive load. While the transmission
line is correctly terminated looking toward the antenna (high return loss), the
transmission line is greatly mismatched looking toward the output circuit of the
transmitter (low return loss). This means that power coming out of the transmitter
is (almost) completely absorbed by the load while interfering signals fed

into
the transmitter are almost completely reflected by the output circuit.
END QUOTE

If the terminating impedance for reflected/reverse power on a transmission line looking back into the PA matched the impedance of that transmission line, it is rather unclear why the PA would reflect _all_ that power back toward the load, rather than dissipate it in that termination.

Yes. It's hard to make a profit when a lot of stores have pulled it
from their shelves.

Now the meth heads have to mail order it:

Don't see why not. Might just have to soak it longer. Fresh lye
works pretty fast and as it becomes depleted it takes longer, so this
would be about the same situation.

I'm not a chemist and don't profess any special knowledge of this
process other than what Iearned eons ago in the "chem lab" in our
engineering lab. We used to do our own aluminum passivation
(Alodine), silver and gold plating and so forth. For example, here's
one of the two-meter amps I've built:

http://k6mhe.com/n7ws/K7CVT_Amp_6.jpg

(Sorry about the quality of the image, this is scanned from an old
snapshot I took just before I polished it up and sold it.)

Before that I worked in my dad's automotive machine shop, where we had
a caustic hot tank for degreasing parts. You learned real fast to not
leave any VW parts in there overnight because the next day, you didn't
have any.

Cecil,

OK, so you don't want to let this drop quite yet. I have dredged through the muck of Google archives, and I found the following 5 exact quotes from you. I believe these fairly represent your position, but if not, please let me know about others. More on the other end . . .

****

1) Quoting Balanis: "Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave antenna currents I(f) and I(b)."

2) Kraus: "A sinusoidal current distribution may be regarded as the standing wave produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along the antenna."

3) From "Fields and Waves ...", by Ramo & Whinnery, in describing the standing wave situation: "The total energy in any length of line a multiple of a quarter wavelength long is constant, *merely interchanging between energy in the electric field of the voltages and energy in the magnetic field of the currents*." Again, proof that standing wave energy doesn't flow. It just stands there being exchanged between the E-fields and the H-fields. That is from page 40 of "Fields and Waves in Communications Electronics", by Ramo, Whinnery, and Van Duzer.

4) I recognize that equation from "Optics", by Hecht. Pick any point, 'z', and see what you get. Hecht says, "It doesn't rotate at all, and the resultant wave it represents *DOESN'T PROGRESS THROUGH SPACE* - it's a standing wave." The RF equivalent of a standing wave of light that doesn't progress through space is an RF standing wave that doesn't

progress through a wire. That's what I have been telling you guys. Standing waves don't move. Standing wave current doesn't flow! Even in empty space, a light standing wave doesn't progress through space, i.e. IT DOESN'T MOVE! That is on page 289 of "Optics", by Hecht, 4th edition.

5) Here's a little help from Hecht of "Optics" fame. (quote)

E(x,t)=2E0t*sin(kx)*cos(wt)

This is the equation for a *standing wave*, as opposed to a traveling wave. Its profile does not move through space; it is clearly not of the (traveling wave) form f(x +/- vt) ...
Let the phasor E1 represent a (traveling) wave to the left, and E2 a (traveling) wave to the right. ... (The sum) doesn't rotate at all, and the resultant wave it represents doesn't progress through space - it's a standing wave. (end quote)

****

Quotes (1) and (2) do not use words that most people would associate with "proof". Instead, the use of terms such as "can be analyzed" and "may be regarded" completely support my position that the choice to use standing waves or traveling waves is simply one of mathematical convenience. When standing waves exist, there is no physical difference between the standing waves and their constituent traveling wave components.

Quotes (3), (4), and (5) completely support my position again. When a standing wave exists, there is no more hidden information buried in the constituent traveling wave components. No flowing energy waves or other such nonsense.

It is possible to have many mathematical descriptions of a physical phenomenon. However, they all need to yield exactly the same physical predictions or else one or more of the models are incomplete or wrong.

Of course there are traveling waves that are not simply mathematical components of standing waves. All of the stuff about TDRs and ghosts falls into that category. This message is not about those traveling waves at all, so you can forget about bringing up all of your TV ghost arguments.

No Tuner i.e. TransMatch -- The SteppIRT vertical is remotely adjustable in length, with continuous coverage from 40 meters through 6 meters - and every frequency in between.

A vertical antenna that is precisely adjustable in length while in the air solves the coverage problem, and in addition has vastly improved performance over existing fixed length verticals. The ability to tune the antenna to a specific frequency results in excellent performance on every band - and this means the entire band, with very low VSWR. Resonant antennas must be made a specific length to operate optimally on a given frequency. So, instead of trying to "trick" the antenna into thinking it is a different length (traps, coils, etc), why not just change the antenna length? This is what we have done with the new SteppIR verticals.

No technical author is going to be arrogant enough to use
the phrases "must be analyzed" or "must be regarded". Many
shortcuts do work from a mathematical standpoint but often
lose their ability to tell us anything about reality.

You were the first person to point that out - that when two
opposite direction traveling waves are superposed, the sum
of the superposition loses its changing phase. That's why
W7EL's and W8JI's phase measurements through a loading coil
on a standing wave antenna were of no value except to prove
that standing wave current doesn't change phase in a wire or
in a coil.

> When standing waves exist, there is no physical difference

of the
>> (traveling wave) form f(x +/- vt) ...

Hecht apparently assumed the definition of the word "not" is
understood by the average reader and didn't need emphasis
so I added it. :-)

There is an obvious physical difference that can be seen
from the equations. Again, a standing wave has fixed phase
while a traveling wave has a variable phase. A standing
wave has a variable amplitude while a traveling wave has
a fixed amplitude. That's two ways they are entirely
different.

> No flowing energy waves or other such nonsense.

Nothing like that assertion is supported in the quotes. Please
point out where any of those references assert that there is no
energy in a reflected wave or that reflected waves do not exist.

Ramo and Whinnery go so far as to vector sum the forward power
flow vector and the reflected power flow vector.

> It is possible to have many mathematical descriptions of a physical
> phenomenon. However, they all need to yield exactly the same physical
> predictions or else one or more of the models are incomplete or wrong.

Plus they need to be linked to reality. Standing waves existing
without the component forward and reverse traveling waves is
divorced from reality. Neither you nor anyone else has been able
to provide even one real-world example of such.

Forward traveling wave + reflected traveling wave = standing wave

What happens to the standing wave when you take away the reflected
wave?

Forward traveling wave + nothing = forward traveling wave

i.e. there is no standing wave. So please tell us again how
you can build a standing wave from a single traveling wave.

> ... so you can forget about bringing up all of your TV ghost
> arguments.

That rug of yours under which you try to sweep all the
reflected energy is going to explode one of these days. :-)

It's a different physical situation. None of this discussion has any bearing on the new problem with only one traveling wave. When you when finally understand the meaning of your own words, there may be hope for progress. Until then, we are just boring everyone.

Hi Richard,
He says it in the last sentence. But here is an example. Take a 50 ohm thevinin source. Power off, it looks like 50 ohms back into it. Take a second thevinin source to represent a reflection and drive 5 volts into the first source. Now set your first source 180 degrees to the reflection and drive forward 5 volts.

(s)-----/\/\/\--------(c)-----/\/\/\--------(r)

(s)source (c)connection (r)reflection. With (s) 180 degrees out of phase from (r), (r) will see a short at (c). It is because of the power generated at the source that the impedance into it can look purely reactive. And, you can use 5 ohms with 1 volt at the source, (c) will still look like a short to (r). The source resistance doesn't matter as long as a 'match' is made.

And for the same reason, why the 50 ohm line doesn't look like 50 ohms is because of reflected power. Drive an open quarter wave line and it looks like a short because the reflected voltage is 180 degrees out from the source.

This analysis is along the lines of the traditional "resonant antennas
work better" line.

Sure, a marconi antenna that is adjusted to be a physical quarter wave on
the operating frequency has a feedpoint impedance that yields a low VSWR
on the coax, and feedline losses are relatively low, but the equivalent
loss resistance of the ground connection is significant relative to the
radiation resistance. A quarter wave marconi requires an extensive earth

system for good efficiency.

My reading of Cebik's article at http://www.cebik.com/gp/gr.html is that simple 4 radial installations have 10 ohms or so loss resistance greater than extensive (128 radial) systems, which themselves aren't zero loss. The modelled feedpoint R varies from 4 to 18 ohms above the radiation resistance of a quarter wave over perfect ground, which implies a feedpoint efficiency of 90% to 66% respectively.

On the other hand, a longer non-resonant radiator (say approaching a half wave) has higher radiation resistance (relative to the equivalent ground loss resistance) which more than offsets the loss expected in a matching network needed to operate the coax at near unity VSWR for low line loss. Not only might the longer radiator be more efficient, but it well have a better pattern (eg higher gain at lower angles or radiation).

It isn't clear to me that the Steppir has "vastly improved performance over existing fixed length verticals" as you put it. With enough radials, it is about as good as good verticals get, but there are other good verticals that don't need as extensive a radial system.

Lets escape from mixed analysis of VSWR in transient scenarios.

Visualise a series circuit of a battery of 100V and negligible internal resistance, a 100 ohm ideal resistor, and an open switch. This circuit is connected to a lossless (ie ideal) transmission line with surge impedance (or characteristic impedance, Zo) of 100 ohms which is open circuit at the far end. It takes T seconds for a wave to travel from one end of the line to the other.

The scenario is a source impedance matched to the transmission line, with unmatched load.

When the switch is closed, current flows into the line. Until t=2T seconds, the current If that flows into the line equals 100V/(100+100 ohms) = 0.5A, during which time the resistor dissipates heat at the rate of I^2*R = 100W. The voltage of the wave Vf travelling from the source is I*Zo = 50V. This situation is constant until t=2T seconds.

At precisely t=T seconds, the wave travelling from the source end reaches the open end of the line, and a reflected wave is established to satisfy the conditions that I at the end of the line must be zero. The reflected wave must have current equal and opposite to the forward wave, so Ir=-If, the negative sign indicates that the wave travels in the opposite direction. Considering the reflected wave, Vr=Zo*Ir = 50V, so the total voltage at the o/c end is Vf+Vr = 50+50 = 100V.

At precisely t=2T seconds, the reflected wave reaches the source end of the line, and the voltage at the line terminals instantly becomes Vf+Vr or 100V. At that instant, the current from the source falls to zero, and the dissipation in the source resistor also falls to zero. This situation continues indefinitely.

My questions are:

How much of the energy that was contained in the reflected wave was dissipated in the source resistor?

Does existence of a reflected wave necessarily increase dissipation in the equivalent source resistance?

Is the reflected wave necessarily absorbed (or partly absorbed) by the equivalent source resistance?

Are the principles that apply to this example inconsistent with the general case (eg dc, ac, transient, steady state etc)?

One word answers should be sufficient.

Owen

I already did, Gene, but here it is again:

forward traveling wave + reverse traveling wave = standing wave

just substitute the appropriate math symbols. There's a
trig identity that corresponds to the above equation.

Take away either the forward traveling wave or the reverse
traveling wave and the standing wave ceases to exist.
There's no valid mathematical model that supports the
position that standing waves can exist with the two
component waves.

Perhaps this URL:

http://www.thekeyboard.org.uk/Quantum%20mechanics.htm

will put everyone on "the same page" and point out that quite a few of
the debates/arguments/discussions here are probably "centered", roughly,
on the same points of dispute/contention ... or, the
unknown/unseen/unmeasured are a mystery that traditional physics
attempts to ignore and gloss over and use "place holders" to compensate
for--yet hamper our complete understanding of forces/affects/effects we
attempt to take for granted and claim a "good understanding" of.

Hey, I probably shouldn't complain--a world without mystery could get a
bit stale--I suppose ...

I didn't want to give the impression that this isn't a significant
improvement over the unloaded vertical on 7MHz.

The Force12 page give an analysis and loosely claims 16dB improvement
over the unloaded antenna, but that is probably based on ignoring ground
resistance again.

Assuming ground resistance of 10 ohms, feedpoint Z would be 15-j460,
ground loss 5dB, line loss 12.2dB, ATU loss ~1.1dB for a total system
loss of 18.3dB.

Improvement from system loss of 18.3dB to 6.4dB is 12dB, a little less
than they might want you to think, but very worthwhile.

Of course results are very sensitive to the ground scenario.

I would have thought the answer was NO, the principles are *not*
inconsistent with the general case.

Or did I use too many negatives?

Hi Owen,
See the example I posted where a pulse is sent down the line. In that case all the energy is dissipated in the source resistor.

Best, Dan.

The principles are those of the behaviour of transmission lines and the theory applying to solving the source circuit. In the 'DC' case, the analysis becomes trivial, but IMHO there were no underlying principles that do not apply in the general case.

The example is a specific case of the general, and the outcome that reflected power is not dissipated in the source resistance dissproves any general statement to the contrary.

You could devise an example with an AC source that had exactly the same outcome, more complicated mathematics to solve it, but the exactly the same outcome. But you don't need to do that, the example is in the set of the general, and stands against a general statement that power reflected from a source is necessarily dissipated in the source.

And I'm not sure I would define those lobes as something other than a compromise. If the lobe is in a good place for you, fine. If not, not so fine.

> Yes, the comparison is between different length antennas, and you are
> right, generally speaking, the longer, the better. (no doubt someone
> can find an exception to the rule, but that isn't the point of this
> discussion.)

I'm a little dense here. 8^) Is a antenna cut for a half wavelength at 80 meters a better antenna at 10 meters than an antenna specifically cut for 10 meters?

I'd also have to go back and look, but isn't the SWR on some bands on the Capacitive reactance end, even though it may be 50 ohms?

I know my old Icom did not like capacitive reactance very much.

The idea that an OCF is superior to a dipole, and certainly Richard's statements would indicate that; makes me wonder why everyone isn't using them!

What I gather from what I read here and all the publications I can get
my hands on it is a quarter wave radiator over 130 radials that are at
least 1/4 wave long.

That may not hold true if you consider radiators longer than 1/4 wave.
"Best" is a very loose spec.

I am in the throws of constructing what I think is "Best" for me. I
started out with a 28 foot radiator and three twenty five foot
radials. It worked. It works a whole lot better now with a total of 36
radials. 14 are about 70 ft, 16 are about 36 ft, 6 are less than 36
ft.

I will work on a taller and more robust radiator next.

I feed it with a SGC-237 tuner. I can only guess the tuner losses are
similar to what a comparable tuner built from the TLW program in the
ARRL Antenna Handbook predict.

The limiting factors are the radiator, the ground and the losses.

What is "Best" for you will depend on your set of compromises.

My expectations are focused on 160-80-40 meters. It was pretty
inexpensive until I added the tuner!

But the point is that I can devise an example with an
AC source that has the opposite outcome simply by using
a Norton equivalent source. When the reflection arrives,
the dissipation doubles.

Dan, I don't deny there may be cases where that may happen, but it is not
true that reflected power is necessarily dissipated (or partly
dissipated) in the equivalent source resistance.

But your underlying principle is that the source steps and doesn't
change. So any general case where the source is at some different level
is now not covered.

Best, Dan.

Of course, pure DC principles are not adequate to cover
general case distributed network problems. Else, there
would have been no need to develop the distributed network
model. How would your transmission line calculator work
if you only used DC principles?

For instance, the conditions at the source are opposite
between the RF frequency where the feedline length is 1/4WL
and the RF frequency where the same feedline length is 1/2WL.

Conditions are also opposite depending upon whether a
Thevenin equivalent or a Norton equivalent is chosen.

Ramo and Whinnery, of "Fields and Waves ..." fame, warn
us not to attach any significance to the dissipation
within those two equivalent circuits. They are still
equivalent even though one is dissipating zero watts
and the other is dissipating 200 watts.

Even when the impedance is the same between the DC problem
and the 1/2WL RF problem, the DC current in the middle of
the feedline is zero while the RF current in the middle
of the 1/2WL section is at a maximum.

Your Norton equivalent doesn't pretend to replicate my (real) source in
every way, it only pretends to supply the same voltage and current to its
load... and it does that.

Dan we are agreed!

My conclusion is that the view put by some that reflected power is
(necessarily) fully or partly dissipated in the PA equivalent source
resistance, (possibly overheating the PA,) is a simplistic view, the

explanation doesn't apply in general and although apparently appealing,
it is wrong.

The question is whether reflected power is ever dissipated
in the source. I can come up with a black box source that
dissipates 100% of the reflected power. All it takes is
a circulator and a load resistor. How does your DC
principles handle a circulator?

The question is: Does any reflected joules/second ever
get dissipated in the PA? To ascertain the answer, one
must calculate the interference patterns in both directions.
If the energy is not dissipated anywhere else, it is
dissipated in the PA.

Is a copper to copper contact always necessary in
an antenna or does solder provide the necessary
continuity when joining wire?

I am disregarding the special case of magnetic
loops where RsubA must be kept low. I am also
disregarding the matter of mechanical integrity.

In my case I am looking at soldering radials to
a piece of copper wire at the base of an antenna, and
also adding a bit of length to the radiating
element.

What about the use of wire nuts to join wires?

The antenna is an HF marconi in an inverted-L configuration.

Thanks for any advice on the matter.

Irv

I'd think you'd want a solid mechanical connection..
Even disregarding mechanical issues, a lightning
discharge would blow apart a soldered connection.
Have you considered using electricians' split bolt
type connectors to make the splices?

Pete

Are you really asking are conductors other than copper (eg solder) are suitable for antennas? I think you know the answer to that.

>
> I am disregarding the special case of magnetic

I note you excluded mechanical integrity, nevertheless...

I suggest you not depend solely on solder for retention of wires. One day, your antenna conductors might be called upon to carry high current (eg lightning), and it might be better if the solder didn't just melt and allow the wires to fall apart.

>
> What about the use of wire nuts to join wires?
>

In some ways, you might as well just twist the wires together. Some wire nuts come with a water+air exclusing medium (grease), but otherwise they are not a lot different to twisting the wires together except they may introduce another metal (in the case of the ones with a metallic spring inside) to the contact mix. Twisting wires together might be more successfull for power applications where there is sufficient voltage to overcome an oxide layer, for RF receive I would use solder or terminals that apply considerable pressure to the joined wires.

Remember that oxided wire connections can cause havoc with receivers and transmitters, the non-linear joint causing harmonic generation and mixing.

2677. coax measurement anomaly ??

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-15 21:37:28 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <KICdnYETH7AGIWTYnZ2dnUVZ_oCmnZ2d@comcast.com>
Source record: 44591

All,

The system is a vector network analyzer and a coax feedline. The analyzer does not have built in 'electronic line length' compensation. So to compensate for 'near' frequency measurements I have created coil of coax on the floor. The theory is when actual measurements are made on the antenna the phase can be normalized by zeroing the phase to the reference coax.

The issue is: Attempts measure the electrical length yield inconsistent results.

The first step was to determine the approximate length. This was done by setting the sweeper to a frequency and counting the phase inversions to the antenna feed - open ended. Lengths of coax were laid out on the floor until the phase inversion pattern was 'very close' visually.

Next the the frequency was set to 200 kc sweep at one meg on the antenna. A near phase inversion was centered on the phase display. Lengths were added or subtracted to the reference coax to get the same center inversion. (The inversion baseline was verified by looking at a larger sweep for reference.) So far so good.

Next the same thing was done at 10 meg. A slight modification to the baseline coax.

Finally the system was retested at 1 meg. Whoops. It was off.

The differences were small, 6 to 8 inches out of an estimated 125 feet. However it is not possible to get a common match between 1 meg and 10 meg - hence the anomaly.

The reference coax is coiled on the floor. Is it possible this created an inductance which affects phase?

Thanks - Dan

ok, take each parasitic element on the yagi, break it in the middle to turn
it into a 'dipole', add a voltage source set at 0v to drive it. now draw

your imaginary boundary. i have satisfied your requirements, now why is my multi-dipole array not a gaussian array by your definition??

Hi Mike,

With all the intervening comments removed, want to reconsider that
again?

An OCF is simply resonant at exactly (by modeling) the same points as
the dipole of the same length. Resonance resides in the wire, not the
drive point. Of Course, F***! (expletive deleted to explain the
meaning of OCF) as the drivepoint is moved through the length, its
fundamental Z (still real) varies from low (at midpoint) to high (near
endpoint) in much the same manner as we would expect for the
difference between a conventional halfwave dipole and conventional
halfwave end-fed. The harmonic drivepoint Zs follow their own
sinusoidal roller coaster through the shift in feed point.

And I say, "Big deal." You can set up any combination of components you wish. The physical reality remains exactly the same as that (fully) represented by the standing wave. You simply cannot derive new reality by manipulating the math.

Source record: 44601

1. The coax has loss, which is different at each frequency.

2. The coax's characteristic impedance is slightly different at each frequency.

3. Fringing at the open end is different at each frequency, so the capacitance at the end and hence the effective length of the coax is different at each frequency.

All of these make it impossible to use a simple model of a lossless coax with fixed impedance for very accurate results.

Coiling it doesn't create inductance or have any other effect on the inside of the coax where, hopefully, the signal from your network analyzer is going.

Hi Owen,

Was your example any more complex, or general? In fact it was heavily tailored for one simplistic answer only wasn't it? The subject line informs us it was.

You have in the past used the dictum that one counter-example devastates a poor hypothesis. What you have here is a two degree answer that fails for the other 358 degrees, where a one word answer is insufficient.

Reduce this to chance for haphazard line lengths and a spectrum of loads, then there's a 50% probability of cooling (absurd of course) and a 50% probability of heating. Reducing that generality to one word would give us "maybe."

The subject becomes 99.44% uninforming.

Hi Irv,

In the Navy, I taught (per the syllabus) that you made a gas-tight
electrical connection between conductors and sealed it with solder.
Solder was not expected to maintain the electrical or mechanical
connection. An example would be a Western Union Splice, then flowed
with solder.

>I am disregarding the special case of magnetic
>loops where RsubA must be kept low. I am also
>disregarding the matter of mechanical integrity.

That pretty much conforms to what I say above. However, having said
that, Lead, Tin and other alloys are usually good conductors when used
in suitable quantity (or with sufficient surface area). There is
nothing wrong with a soldered joint in a magnetic loop, although a
soldered loop can easily be done poorly.

There are other issues of weathering of solder, and galvanic
reactions. This argues sealing the solder with rubber or synthetic
coating, and/or examining the metals involved. This is usually a rare
issue to be concerned about.

They enforce the gas-tight connection and preserve the seal of that
interface through spring force, but usually in a dry environment (I
suppose you can find weather proof versions).

Thanks Pete -- I'm not really concerned about mechanical connection
as there will be no physical strain. Yes! I am definitely considering
'split bolt' (I call them wire nuts -- not sure where I got the
expression).

I must have had a Senior's moment. I was thinking of a mechanical
joint rather than a soldered one. In a magloop, which is one of the
projects I'm working on now, I plan to use copper and silver-solder for
sure.
>

As per Owen's post I will consider a sealant or protection of some
sort. In any event, the major effort is installing radials which
will be soldered to a ring of copper wire around the base of the
antenna -- it will be readily accessible for inspection and
repair if required. I don't want to have to to that too often

though -- and I sure as heck don't want to run out and dig through
the snow when it's 30 below! :-)

Wire nuts with suitable protective coating after connection
may just be the easiest way to go. I only want to put out
8 radials. As for the radiating element, it doesn't have a lot
of strain on it either, but I think for temporary testing I'll just
use a quick twist of the wire and solder it until I find the
length I want -- then I'll do a Western Union bit with just a
few turns, then solder flood it. It is #12 and shouldn't
be a problem to twist in a fancy manner.

Thanks for the ideas.

Here is a picture of what most of us understand to be wire nuts:
http://cableorganizer.com/wire-connectors/

Quite a different thing to split bolt line taps.
http://www.vk1od.net/post/post04.jpg shows a split bolt on the earth
electrode.

My comments about wire nuts were about wire nuts as most of us understand.

I would not use wire nuts for your earth system.

Split bolt connectors are fine for your purpose.

Art said "Remember at the
cessation of time all movement of flux stops.

When is this going to happen. If it is anytime soon I need to
seriously re-evaluate my retirement plans.((:<))==

Split bolt electrical connectors look like this Stateside:

http://ebusiness.ilsco.com/webapp/wcs/stores/servlet/CategoryDisplay?storeId=10001&langId=-1&catalogId=1&categoryId=1

Used a lot for electrical connections to utility power transformers,
etc.

Yes Pete, same as I showed, but better detail in your pic. Insulating
covers are also available which sort of hides the internals.

Yes, it is a nightmare, I have heard at some hospitals in so. calif.
that the birth rate in some hospitals is 80% illegal alien children. If
the tax payers are so free with their money, maybe they would like to
pay for my grand childrens' children to be born? Wonder if anyone
notices it is driving medical costs SKY HIGH???

Hey, it never hurts to ask! <ROFLOL>

Do us a favor, compute the S-vectors for an incandescent lamp with a linear
filament.
Then follow though with the same for a transmitter, transmission line and a
mismatched load.
You will find that is the reflected S-vector that adds heat to the plate.

Poppycock, TV ghosting is caused by multipath length differences. Calculate the position ratio and the horizontal scan frequency (15750 Hz is close enough). That gives you the path length difference; it is generally on the order of miles (= major terrain features).

Thanks for the learnin' sir! Now I know, and I wouldn't
use wire nuts either! I'm even leery about them in my
house wiring! The split-bolt connector is what I had in
mind.

Thanks again

"Telltale signs are everywhere -from the unexpected persistence and
thickness of pack ice in the
waters around Iceland to the southward migration of a warmth-loving creature
like the armadillo from the
Midwest.Since the 1940s the mean global temperature has dropped about 2.7°
F."

The quotation above is from Time Magazine, June 24, 1974. They had a
feature article than included this dire warning: "But there is a peril more
immediate than the prospect of another ice age. Even if temperature and
rainfall patterns change only slightly in the near future in one or more of
the three major grain-exporting countries-the U.S., Canada and
Australia -global food stores would be sharply reduced."

Hey, man -- pick your peril ... and then hype it until you can't hype it no
mo'.

Your pic reminded me, somewhere in all the junk ther are 4 35 ft long
steel street lamp poles. I know I have made the place sound like a
junk yard but it isnt by a long way. Most of this stuff is inside a 30
x 60 ft building that you could drive a big motorhome into.

Analog TV ghosts can be produced within the TV transmit antenna system as well as by reflections of the transmitted signal in the propagation environment. I know this from my experience as an RCA Broadcast Field Engineer, because I've evaluated and corrected many transmit antenna systems that had been the source of such ghosts.

For example, a reflection from a mismatch between a 1,000 foot long, air-dielectric transmission line and the TV transmit antenna connected to it produces a ghost with ~ 2 µs delay from the main image. The active scan width of an NTSC TV line is about 53 µs, so 2/53 = ~4% of the width of the screen, or maybe 5% counting overscan. This ghost is easy to see in a typical TV set/viewing setup.

Wrong, wrong, wrong. Energy is not created or destroyed, but it can be
converted back and forth to mass. See mass defect and hydrogen fusion.

Less wrong, line length makes no significant difference (unless it is really
lossy).

Wrong, wrong, wrong again. Transmission line impedance is strictly a matter
of physical dimensions, and surrounding materials permitivity and
permeablity.

Richard,

It would seem a short might reduce some end capacitive effects when
compared with an open circuit. However it would not help in the case of
'minor' frequency dependent changes in coax inductance.

Thanks,
Dan

Yep, Danny has some good stuff there.

I tried sending a similar message to this before but this horrible
Google Groups swallowed it somewhere.

Another related resource would be Leeson's book, "Physical Design of
Yagi Antennas." Clearly, you are not designing a Yagi, but a lot of
the material strength, deflection, wind loading, etc is applicable.

There was also an Excel workbook offered by ARRL to accompany the
book. I have it someplace, but can't lay my hand on it at the moment.

Once you get the above ground part designed, you need to worry about
the anchor too. Here's a link to a paper that might help there:

We performed that exact experiment at Texas A&M
in the 50's. The ghosts were right where the
reflected waves predicted they would be. I
wonder how the modulation in a reflected wave
moves up and down the line without the reflected
wave also moving up and down the line? :-)

Which brings us back to the great loading coil dispute.

In the resonant quarter wave monopole (say 80m), loaded with solenoid coil, about 2/3 up the radiator, we experience significant (about 40%) current drop at the top end of the coil. This is also demonstrated by bottom of the coil getting warmer or hot proportionately, indicating that we have standing wave circuit and some real current in the system, fortifying Cecil's argument. RF is flowing along the radiator, "seeing" high impedance tip at the end, being reflected, flowing back and being superimposed with the forward wave. Reality that W8JI and other "defenders" had hard time to swallow.

In the case of traveling wave antenna, like Beverage, terminated with resistance, we can see the uniform current along the wire. Coil or slinky inserted in such system will show the same current along the coil (minus ohmic losses).

There is real life proof about what Cecil is saying above.

Relating to the standing wave circuit, I had question in my mind: how important is to control the resistance and consider it in standing wave antenna system. Example is that the current above the loading coil is

appreciably smaller than at the base, hinting that you perhaps do not need low resistance (copper tubing vs. SS whip).

But...
if the standing wave is made of forward and reverse traveling waves, should not we be trying to keep the resistance low in the system? Or is it insignificant?
My pet peeve tells me that it would gain significance in the multi element loaded arrays. Do the modeling programs capture that? They show slight increase of current at the bottom (few turns) of the coil (when loading inductance is properly modeled). Would that be due to the loss from that point on, when forward and reflected wave is "meeting" the losses to resistance and radiation and then with lesser amplitude superimposing with forward wave?

Yuri, K3BU.us

The I^2*R losses in the conductors depend upon the net current which is the phasor sum of the forward current and reflected current. Since the net current is lower above the coil in a mobile center-loaded antenna, the resistance of the stinger is not as important as the resistance of the bottom shaft which carries maximum current. Whether the I^2*R losses in a stinger are significant or not is a subjective call. If one is looking for that last 0.1 dB that will win a mobile antenna shootout, replacing the stainless steel stinger with one-inch copper tubing might do the trick.

Incidentally, in a thin-wire 1/2WL dipole, the reflected current arriving back at the feedpoint is approximately 90% of the forward current, i.e. only about 10% of the current is lost to radiation in its round trip to the end of the antenna and back. The same is true of forward and reflected voltage. The feedpoint impedance of a 1/2WL dipole results from the superposition of and interference between the forward and reflected waves on the standing-wave antenna at the feedpoint.

If we made a Z0=600 ohm 1/4WL open stub out of resistance wire such that the feedpoint impedance is 73 ohms, we would have a pretty good simulation of an antenna where energy is converted to heat instead of being radiated. The voltages and currents on the stub would correlate closely with the voltages and currents on a 1/2WL dipole.

Examples in use for many decades already are the directional arrays used in AM broadcasting, where all elements (towers) in the array are driven. The element spacings & orientations, and the relative power & phase applied to each element determine the net radiation pattern of the array.

Hi Dan,

A short "might reduce some?" That is rather an understatement.

"It would not help... 'minor' changes?" That is even worse.

Trying a short in place of an open would have taken less time, and
proven these two statements are wrong. A short is also an excellent
way to measure Ohmic loss in the cable. If you read your user's
manual for your vector network analyzer (assuming it has one), you
would find that a short is the preferred method. Also, for vector
network analyzers that do not have built in correction, it is also
expected you repeat the measurement with a Zc load. Then, and only
then do you proceed to doing it with an open (which will reveal the
extent of fringing).

I wouldn't do an open anyway. Instead, I would measure a load
constructed to mimic the measurable (you must have some idea what it
is you are going to be measuring, don't you?) and put it in a shielded
enclosure. Then move this text fixture to the vector network analyzer
and repeat to see the effects of the line.

Message-ID: <au-dnYkOdYzofGfYnZ2dnUVZ8rOdnZ2d@bt.com>
Source record: 44537

What is displacement current? Antenna and electromagnetic books talk of displacement current flowing in an insulator or dielectric and providing a magnetic field like a real current. They make out that the magnetic field is distributed the same way as if a real current was flowing along a conductor. Displacement current is called a virtual current. Books refer to a real current flowing in a conductor, and being converted to a displacement current where the conductor stops. Wikepedia says that displacement current is proportional to the time derivative of the changing electric field, where a changing electric field induces a changing magnetic field. Diagrams show displacement currents flowing through the air in the near field of the antenna. Some scientists believe that displacement current is formed by virtual photons. It appears that virtual photons are hard to investigate in particle accelerators.

Displacement current is usually introduced as the virtual current that flows through the dielectric of a capacitor. Does such a current really exist?

Sometimes it is best to back into the correct answer... The suppliers
are going to charge me for 5 yards of concrete in my area whether I
use it or not...
The other choice is to mix it myself.

When one discharges a charged capacitor through a resistor,
the excess charge from one plate of the capacitor flows
through the resistor to the other plate of the capacitor
in order to equalize the charge on both plates. Since the
current is supposed to be the same all around a single
series circuit, it is *as if* current is flowing through
the capacitor's dielectric somewhat like current flows
through acid inside a car battery. Since actual current
flowing through the insulating dielectric would destroy
it, of course that current is only virtual and is called
displacement current. It can usually be treated *as if*
it were real.

It was about the same around here. I only wanted about a yard and where I wanted it a truck could not get in very easy. Had 50 bags (90 lb bags) delivered for around $ 300. Then rented a mixer for about $ 40. Spent about 6 hours transporting the bags with my riding lawnmower and cart about 150 feet to the tower hole and mixing it up and then cleaning the mixer. I did have water and electricity at the hole. Only put one bag in the mixer at a time as that was all I thought I could handle by myself. Used 43 bags in the tower and spent another part of a day putting the other bags in holes and pipes for the guy wires. It would have been cheeper to just get a load delivered and much faster, but just could not get a truck back there and I just could not see wheelborrowing it to the hole .

Here's a fascinating (and, at the time, controversial) take on Maxwell's
displacement current, originally published in Wireless World:

"The concept of displacement current, or displacement current density,
was introduced by James Clerk Maxwell to account for the production of
magnetic fields in empty space. Here the conduction current is zero, and
the magnetic fields are due entirely to displacement currents." - Kraus,
Electromagnetics

There are two kinds of current, both arguably "real". One is
conventional or conduction current. This is the flow of charge from one
one point to another. The conventional current is the rate of charge
flow -- one ampere of current equals one coulomb of charge per second.(*)

The other kind of current is displacement current. This is the rate of
change of electric (field) flux passing through a surface. James Maxwell
is usually credited with connecting the two; his equations show that a
time-varying conduction current gives rise to a displacement current,
and vice-versa. Conduction current consisting of charge moving onto and
off a capacitor's plates creates displacement current within the
capacitor's dielectric, which then creates conduction current in the
plates on the other side. The effect is just as though charges are
moving right through the dielectric, although they don't. Only fields
move through the dielectric, constituting the displacement current.

(*) Although "conduction current" usually refers to charge flowing in a
conductor, charge can also flow through space or non-conducting
materials, as for example the electron beam of a CRT. This is a
conventional or conduction current, but sometimes called a "convection
current" when in space.

has it been that many posts? i'll bet you just searched for the alias i use on here, which is a common anti-spam alias used by many posters. i use only the one alias, though i did just recently switch isp's so the posting server has changed, oh and i do occasionally post via news.microsoft.com for some of their software development groups. if you really wanted to find out who i was you would have found it already... its right there if you really want it. every header (at least from this isp) has the real identity in it.

I seem to remember a capacitor defying gravity via displacement
current but I can't remember the details. Do you recall that Cecil?

You might want to see if you can rent a 1 yard cement delivery trailer.
Some tool rentals have them.

I was putting you about 100 to 140 miles North by Northwest of London.
I suppose that would be towards the Derby area .

What is the strength of "mix it yourself" concrete? You might need the five yards!

Down here, "mix it yourself" costs more than readymix (provided you are near a readymix plant), and if you "measure" the mix with a shovel, it will be rated lower in strength. If you mix it in a barrow, even worse.

Mea culpa. I did indeed type "calcium carbonate", while of course the "TSP substitute" -- "washing soda" -- is *sodium* carbonate. At least I gave the correct formula. I apologize for the error. Yes, I'm sure the "soda" is from sodium, as in "caustic soda" which is sodium hydroxide (lye) and "baking soda", which is sodium bicarbonate.

where is violence advocated?

well MD claims that in asking what problems see with the fact you can
pass the written test while missing all the rules and reg question is
advocating no change at all

"art" quoting RF:
>> All you need to do then is to prove it, and get the FCC to accept it.
>>
>> RF
>
> What about the use of complex circuitry methods od design does that
> present any advantage? We now can insert lumped constants ?

Note the responsible party in this, which I re-post below with emphasis:

"All __YOU__ need to do then is to prove it,..."

If YOU, Art Unwin, want to be recogniz(s)ed for introducing a new application or concept about "Irregular Gaussian Radiation Fields," shouldn't that first be based upon your own theoretical and experimental research and proofs, which after your publication of same, are capable of being proven true by other scientific investigators?

If both of those situations exist, then maybe you will have a chance for the commercial and governmental acceptance/success of your concepts, and your personal recognition for the same.

But until then, you may wish to keep such revelations closer to your vest.

With respect to your claimed English background, I wish you the best, Sir, and
remain your humble and obedient servant etc, etc,

Hi Roy,

With regard to "James Maxwell is usually credited with connecting the two; his equations show that a time-varying conduction current gives rise to a displacement current, and vice-versa," need it be time-varying? I haven't given this a lot of thought in the past, but it appears to me that the laws cover the case of a constant current as well. If I'm not mistaken, which I could well be in this case, it's a time-varying electric field that "looks like" a current, and an electric field whose time derivative is constant "looks like" a constant current, at least with respect to the magnetic field to which it gives rise.

Cheers,
Tom

One is to step down the feedpoint impedance and the
other is to choke common-mode current.

I'll be glad to defer to you on this. But it's important to see that the static field produced by a constant conduction current won't induce a conduction current in another conductor. So there's no static equivalent of what happens in a capacitor, which behaves as though the charge seemingly flows through the dielectric.

Thanks Tom for the extract from King etc.

They make it very clear when they state:

"The operation of the shielded loop is explained popularly by first stating that the desired loop current is due to the magnetic field, and then maintaining that the metal shield cannot be penetrated by the electric field but can be penetrated by the magnetic field. All these arguments are incorrect in the light of fundamental electromagnetic principles."

Thanks again for your valuable help... Owen

Del cross H = j + dD/dt (pretend the lower case "d"s are the Greek letters
for partial differentiation). "dD/dt" is supposed to represent the
displacement current. Some people don't like the term "displacement
current" (Feynman), so be careful where you use it.

2760. Best Yagi impedance

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-17 02:20:10 UTC
From: ve2pid <ve2pid@videotron.ca>
Message-ID: <1174098010.745176.35010@e65g2000hsc.googlegroups.com>
Source record: 44575

Hi to all,

I read somewhere that, in the case of Yagis, ''in the range of 25-35
Ohm you get the
best balance between gain, pattern, bandwidth and element currents.'''

Is that true? And if so, I would like to have the theoretical
explanation behind this.

Thanks and 73 de Pierre ve2pid@videotron.ca

2761. Re: Best Yagi impedance

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-17 02:56:57 UTC

Message-ID: <12vmm7s177gmm8c@corp.supernews.com>
Source record: 44477

Sorry, there's no theoretical basis for declaring what the "best balance" of those parameters is. So there's no theoretical basis for deciding what the feedpoint impedance will be for the "best balance".

But. . .

If the Yagi impedance is very low, it indicates very strong coupling between elements and high element currents. This indicates a sharply tuned antenna which might have high gain if the losses are minimized, but also narrow bandwidth. This is a common result of trying to squeeze too much gain from too small an antenna. To understand why, try googling "super gain" or "supergain" antennas or look this topic up in an antenna text.

If the Yagi impedance is high -- close to that of a dipole -- it means that there's very little coupling from the driven element to the parasitic elements. Consequently, the parasitic elements won't have much current with which to produce fields, and they won't do much. The antenna won't have much gain relative to a dipole, and its pattern won't be much different from a dipole.

So while a Yagi having an impedance outside very roughly the 25 - 35 ohm range can still perform well in one or more respects, you should look carefully at it to see what tradeoffs have been made.

Of course, this applies only to the resonant feedpoint resistance at the center of the driven element, which can be transformed over quite a wide range by various structures and networks.

Finally, the above comments are pretty broad generalizations, so they're subject to numerous exceptions. But they're a good starting point for understanding some basic properties of Yagis, and hold often enough to be reasonable rules of thumb.

I don't understand why there is such a relationship, if there is.

Yagis are often designed for a feedpoint impedance that is relatively
easily transformed to 50 ohms for the main transmission line.

A quarter wave transformer from 28 ohms to 50 ohms is relatively easily
made from two parallel 75 ohm lines. Perhaps that is the attraction to
the impedance range you mention.

Owen

I don't think there is such a relationship either. The feedpoint impedance is part of the results from the design process, along with the gain, pattern and beamwidth; but it does not determine any of those other properties.

The so-called "best balance" between all these properties will depend entirely on the personal priorities of the designer or the user. (Antenna optimization software demands very clear instructions about this, and forces you to think very hard about what you really mean by "best".)

Many good designs do have a feedpoint impedance in that 25-35 ohms region; but so do some real lemons, too, so it isn't a reliable indicator.

As Roy says, yagis with much lower feedpoint impedances tend to have high internal (I^2*R) losses, which increase rapidly as the impedance falls and element currents rise. Those can be classified as poor designs, simply because there are plenty of better alternatives.

Also, it is possible with many designs to increase the feedpoint impedance towards 50 ohms by adding a director at very close spacing (about 0.05 wl). That director has relatively little effect on other performance parameters, so it can be added fairly late in the design process as a means of matching. (After construction, that close-spaced director also allows final adjustment of the matching, by bending the ends towards or away from the driven element.)

>Yagis are often designed for a feedpoint impedance that is relatively
>easily transformed to 50 ohms for the main transmission line.
>

>A quarter wave transformer from 28 ohms to 50 ohms is relatively easily
>made from two parallel 75 ohm lines. Perhaps that is the attraction to
>the impedance range you mention.

That is a very reasonable strategy: if the impedance comes somewhere
close to a convenient value for matching, then optimize it to exactly
that value.

For example, DK7ZB has developed a range of yagi designs optimized for
28 ohms. There are links to these and several other designs from:
http://www.ifwtech.co.uk/g3sek/diy-yagi/index.htm

Message-ID: <1174132397.263659.145770@d57g2000hsg.googlegroups.com>
Source record: 44483

Well, Feynman might have been impressed with the 'displacement'
currents we are currently generating across the variable cap of a
parallel tuned circuit at 14 megacycles... Acrylic will droop and melt
in seconds and glass heats so rapidly it shatters almost instantly
when the RF is keyed... Yes, I can be convinced that there is no real
'current' flowing, in that no electrons are passing through the
dielectric (i.e. we don't get an arc until the dielectric fails)...
But, the varying electric field across the dielectric as the cap
plates load and unload electrons is certainly pumping the outer
electrons in the dielectric rapidly enough that they dump off
considerable heat as they change state...
Did you know that you can heat an acrylic plate of 0.125" thickness so
fast and so hard that the acrylic boils in the center of the plate,
leaving frozen cavitation bubbles behind when the RF is cut off, while
the faces of the plate remain smooth and shiny? Amazing to look at...

Meanwhile, back to the drawing board...

Awww come on Cecil - think it through...
First the standing wave is only standing by stroboscopic effect, i.e.
the instantaneous alignment (constructive and destructive) of the
forward and reflected wave fronts at a given point along the line...
The currents continue to stream past the standing point (in both
directions) carrying both the carrier and it's instantaneous
modulation products with it...
Also, the ghosts should be multiple... In the example cited of 2 uS
delay, there should be a ghost every 2 uS across the screen, albeit
each subsequent ghost a fixed number of dB weaker that the one before
due to the % radiated (plus line losses) for each round trip...

OK, I'll change my wondering - I wonder how any rational
person can believe that the modulation in a reflected wave
moves up and down the line without the reflected wave also
moving up and down the line? :-)

Yes, that's exactly the way it appeared to be. Multiple
ghosting getting fainter across the screen.

The ghost image needs to be at least 1% of the peak amplitude possible for the primary video signal before it becomes noticeable So in order for the 2nd and successive ghosts in my example to be visible to a TV viewer, the reflection producing the first ghost would be so objectionable that a TV station would not tolerate it, and fix the problem.

Yes. Point is the a-c amplitudes of both forward and reflected currents are varing at the r-f frequency but their phase relationship is fixed so that the two currents may be represented by vectors (phasors) at the point.

Amplitude modulation is a mixing process which produces sum and difference frequencies that are not synchronized with either original frequency. Stable frequency generators produce fixed locations for maxima and minima along the transmission line, however.

Cecil`s tests were designed to demonstrate atanding waves and phasor addition. They likely worked as intended.

When we design antennas, we try to optimize the design for desired gain, F/B, bandwidth. The impedance is secondary consideration, we can match it to the feedline, but any transformation, matching adds losses. All the parameters are interdependent and we can always try to aim for the best desired compromise. In a typical Yagi, as Roy indicated we end up with range of impedances that are appropriate for particular design.

I realized that Yagi has low impedance and I generally do not like any matching and introducing unnecessary loses. The way for maximum gain, clean pattern, great F/B, 50 ohm feedpoint impedance and no matching gizmos to me was to go Quad and Quad/Yagi element combinations. Quads have higher impedance and by adding elements, the impedance would drop to around 50 ohms.
My design goals were to in order of priorities: close to 50 ohms impedance, best possible clean pattern and F/B, broad bandwidth and maximum gain. I prefer better pattern over max gain. In order to get max gain one can tweak the design for about +- 1 dB, while differences in major vs. minor lobes can be in order of 10s dBs, which means much better S/N ratio and capability to

dig weak signals.
The results was series of designs from 3 el Quad, through 5 el. Razor (3Q, 2 Y), to 7 (8, 10) element Razors with log cell driven element and quad and yagi parasitic elements, while achieving 50 ohm feedpoint.
I would not claim that 50 ohm was the indicative of best performance design and should be considered "rule" for design, but that I managed to optimize the arrays for best performance and minimum loses while achieving 50 ohms.
Later, when I wanted to further improve the designs or check them in software modeling (the original designs were done on 2m antenna test range) and started with 3 el Quad comparison and optimization, the results were off and I did not get the chance to go back and follow the process in soft and hard modeling and see where the discrepancies are.
Pictures of my 15m 7 el. stacked Log Razors are at
http://www.k3bu.us/razor_beams.htm
showing the 7 el. design having Yagi Reflector, Quad Reflector, dual Quad driven log cell, Quad Director and two Yagi directors. Impedance was 50 ohms and SWR 1:1.1 at the band edges. In real life, the Razors were head and shoulders above the Yagi variety and helped me to cream bunch of world records from VE3BMV.
So I guess the lesson is, one can achieve desired compromise and use any of the design parameters as priority and work around, but there are limitations as what would be the results. Back to Yagi, as Roy outlined, You could have 50 ohm dipole like Yagi (lousy F/B and gain, but "good" impedance and match) or great pattern and gain at the price of lower impedance and some lossy matching, which still outweighs the former.

As I remember, the Texas A&M experiment used a reflection
coefficient of 0.707, i.e. 50% of the signal energy was
reflected at the TV receiver. There also had to be considerable
reflections at the source but that fact was never discussed.

David wrote:
"Does such a current really exist?"

Yes. The sun is shining brightly here, so light is propagating in the void between the sun and the earth. Normally this void does not conduct such electric current as is involved in the energy flow from the sun. Light is an EM wave.

EM wave propagationin a void requires a magnetic field to generate an electric field which in turn generates a magnetic field and so on ad infinitum.

The ability of a charge to repel a like charge at a distance without conduction is displacement. It`s how a varying charge moves through a capacitor which passes a current.

Hello Art,
Having a patent does not mean that one have something that really
works.

I did a survey on patents in the field of Electronic Article
Surveillance (EAS) and Sailboard Fins. Many of the patents I saw, are
useless, seen from a technical perspective. The problem with those
technically useless patents is that when you invent some really nice
operating principle, you may interfere with such a patent. In that
case it is the available money that counts only.

So for me, to be involved in a patent application does not support the
fitness of a new theory.

I'm one of the pseudo-experts that posted to one of your "very deep
question" on Faraday Rotation in NEC2 and/or NEC4.

Best Regards,

Wim

To get an electric field with a constant time derivative, you need an electric field that is forever slewing linearly. You need to keep piling electrons onto one plate of the capacitor forever. So, you're right that a constant conduction current can give rise to a constant displacement current, but in any real capacitor with a breakdown voltage, you can't get this to happen for very long, so it doesn't have much applicability in any real system, and wouldn't get talked about too much.

One fact to note is that the virtual impedance changes
all up and down a transmission line yet no additional
reflections occur while the Z0 is constant. Reflections
occur only at *actual* impedance discontinuities, e.g. at
a junction of two different Z0s.

Well, when I posted the above quoted material, I actually gave that some thought. I have some 0.1uF polypropylene caps that I've been testing for self-discharge. Their self-discharge time constant is on the order of 50 to 100 YEARS. Polyprop is a good dielectric, but not the best (lowest leakage) available. So I considered that it's quite possible to charge a 1uF capacitor with a constant current of, say, 1e-14 amps for longer than I'll live, and only reach 3 volts or so, with negligible error from leakage currents. That comes pretty close to DC, as far as I'm concerned. It's still not DC on a geological time scale, but it is on a human life-span one--and for sure it's DC with respect to my attention span for tracking such things!

Cheers,
Tom

Cecil, that is a simple statement of a scenario in which reflections
may occur, but *not always* occur.

Think about it and you will think of examples where a reflection does not
occur at the "junction of two Zos".

I am not quite sure what you mean by an "impedance discontinuity" beyond
the simple "junction of two different Zos" case.

The magnitude of a reflection (zero or otherwise) is *always* and *only*
related to whether the ratio of V to I for the "thing" (whether it is
another line, a lumped circuit or some combination) attached to the end
of the line is equal to Zo. The magnitude is calculated from V/I (Zl) and
Zo using a well known expression.

Should your "rule" be more correctly stated as Reflections
may occur only at *actual* impedance discontinuities, e.g. at a junction
of two different Z0s. Since it has "may" in there, it isn't a rule, is it
worth stating? It is just one of those "may"s that people like to parrot
until they become a Rule of Thumb (ROT).

I've reviewed many patents in the course of my regular employment and as a consultant. Large numbers of them describe "inventions" that can't work at all, don't work as described, and/or don't solve the problems they're alleged to. It's clear that on very many occasions, neither the inventor, the patent attorney, nor the examiner understand the principles involved. The general practice seems to be to issue the patent unless there's a clear and obvious conflict with an existing patent or current art, then let the markeplace sort out the validity. There are no Einsteins at work in our patent office!

One of my favorites is U.S. patent #6,025,810, "Hyper-Light_Speed Antenna" (Strom). Besides sending the signal at a speed faster than light and penetrating known RF shielding devices, a side benefit is that it can be used to accelerate plant growth. I've read many patents which are as fundamentally flawed, but this one has the advantage of being so obviously wacko that nearly anyone but the overly credulous can see from it just how little a patent really means as an indication of technical merit.

I assume you are talking about virtual reflection
coefficients based on virtual V/I impedances, something
that has gotten hams into conceptual trouble for any
number of years. Let's take a look at the S-Parameter
equations.

```
Port 1 | Port 2
---Z0---+---Z1---
a1--> | <--a2
<--b1 | b2-->
```

```
b1 = s11*a1 + s12*a2
b2 = s21*a1 + s22*a2
```

As you probably know, s11 is a *physical* reflection
coefficient involving unequal impedances.
s11 = (Z1-Z0)/(Z1+Z0)
Z0 and Z1 are physical impedances, not virtual
impedances, i.e. *NOT* merely a V/I ratio.

a1 is the voltage wave incident upon Port 1.
s11*a1 is the reflection from Port 1.

If Z1 <> Z0, there exists an impedance discontinuity.
s11 <> 0, and s11*a1 <> 0, i.e. there exist reflections.
This is why I say: If there is a physical impedance
discontinuity, then reflections exist.

If reflections are to be canceled, then s12*a2
must be equal in magnitude and 180 degrees out of
phase with reflection s11*a1. Note that for
reflections to be canceled, they must first exist.

s12*a2 is the voltage not reflected from Port 2.

All this is covered in HP Application Note 95-1,
"S-Parameter Techniques" available from:

http://www.sss-mag.com/pdf/an-95-1.pdf

Tom, I read your description of that experiment on the web some time ago
and found it fascinating. As I recall, you used a 3456A for your
measurements. You might want to post a link to your writeup.

Sorry for the delay in response Richard, but as a confessed not-so-wise guy, I've gone back to modeling to see exactly where I've erred and to discover the source of my density.

And darned if I can't figure it out!

I've modeled Both OCF and frequency cut dipoles, and darned if the frequency cut dipoles don't look better.

Your argument makes it sound as if the OCF has identical performance at those same points as a frequency cut dipole. Resonance or not, there are bands for which I still need a tuner, which makes the whole purpose a little moot. The SWR curve of the OCF really doesn't look all that hot, sometimes it is just passable at the frequencies of interest,and looks better off frequency. and it looks like something a radio with a *good* autotuner could take care of. That has been my experience with them. Sure seems like a compromise to me. YMMV.

Mike,

You seem to be considering just the flat-top of the OCF and that is not the only conductor of an OCF dipole antenna system carrying current, the other is the feedline.

If you offset the source in a halfwave dipole (zero length feedline), I expect you will just see an increase in feed point R, and no significant change in loss. So on that basis you could argue they are equivalent... but you haven't compared an OCF dipole antenna system with a centre fed dipole antenna system.

Then you talk about the SWR curve and ATU.

Aren't you trying to compare the entire system? Is there much point in comparing the flat-top of an OCF with a centre fed, it is only part of the picture.

Of course, the system performance will depend on assumptions that you make about the ground, feedline route, length, type, ATU etc... but having chosen a scenario, you can get to an overall performance figure

that properly deals with the complex interaction between components.

Yuri, that is your approach, but it is not the only one.

Others of us quantify the expected transformation losses, and add them into the gain equation to deal with the effects, making a design selection on a rational basis rather that just excluding a whole bunch of solutions because of a prejudice about matching loss.

Hi Mike,

Well, there are two "performances" to consider (and not just the
matinee and the evening show).

>Resonance or not, there are
>bands for which I still need a tuner, which makes the whole purpose a
>little moot.

For that, the tuner will be called to perform different chores for
different bands for different offsets. However, the resonances will
fall principally at the same frequencies.

>The SWR curve of the OCF really doesn't look all that hot,
>sometimes it is just passable at the frequencies of interest,and looks
>better off frequency.

Much the same could be said for any garden variety dipole.

> and it looks like something a radio with a *good*
>autotuner could take care of.

Much the same could be said for any garden variety dipole.

>That has been my experience with them.
>Sure seems like a compromise to me. YMMV.

Much the same could be said for any garden variety dipole.

The two performances would be tune-up and launch characteristics. If
modeling is any indication, the offset affects the magnitude of the R
at resonance (again, no different an experiance comparing a normally
fed half-wave dipole to an end-fed half-wave dipole). However, the
gain, number of nulls (or lobes) does vary at the higher frequencies
when offset is added to the variables. Higher gains for the near
end-fed (albeit 1dB).

The "eliminate the transmission line" sword cuts both
ways. If the source cannot tell the difference between
driving a one wavelength transmission line and driving
a lumped circuit load directly, it follows that the load
cannot tell if it is being driven by a one-wavelength
transmission line or being driven directly by a source.
The incident signal looks the same in either case and the
load rejects (reflects) the same amount of forward power
either way. Except for the energy stored in the one-
wavelength transmission line, conditions are the same
in either case.

Richard-

Someone asked that if the OCF Dipole was so good, why didn't everyone use one? When I got my start back in the 50s, everyone did use one. I used my "Full Windom" for several years on 80/75/40/10 CW and AM. In today's world, the G5RV antenna appears to have taken over as the popular antenna of choice, and is probably equally as bad as the OCF Dipole.

As a teenager I knew little about SWR. I used a balanced tuner to match the 300 Ohm feed-line, tuning for maximum brightness of a pilot lamp connected to a loop of wire taped to the feed-line. I understood that the feed-point was chosen so impedance was reasonably close to 300 Ohms on all bands except 15 Meters. Your reference to a roller coaster suggests that it might not be reasonably close.

Using the modeling software, is there a feed-point where impedance is close to an available balanced feed-line on multiple bands? As close, I would accept a 2:1 SWR.

Hi Fred,

The usual designs include a BalUn that transforms from a higher drive
Z to the 50 Ohms of a line. In that sense, the Off Center Dipole
introduces accessible resonances at every harmonic instead of at odd
harmonics. Depending upon the offset, some come into play, some go
out and for a variety of transformations. Some suggest 2:1, others
4:1, and yet others higher.

And you would still need to decouple the line (if the BalUn design
doesn't already answer that). Given the field imbalance, it may
require an aggressive decoupling (a second choke, or a distributed
choking). I have a large document available to those whose mail box
can stand the load.

> Roy Lewallen, W7EL

I've used washing soda in laundy. It is very alkaline, but I'm not
sure it would have much effect on aluminum.

Sodium hydroxide, NaOH, definitely eats aluminum. I use it in
various applications around the lab. Red Devil is no longer
available due to the meth heads, but I found a private Loblaws brand
that works just as good. The ingredients on the label are sodium
hydroxide, sodium silicate, and chlorine bleach.

You can tell the approximate strength by pouring a bit in a glass
and adding some canning salt. If the salt doesn't want to dissolve,
the solution is pretty much saturated at above 32%. Also, when you
first open it, you might notice a small wisp of condensation above
the lip, and a strong pungent smell.

If you let some dry on a glass surface, it is a bit difficult to
wash off with plain water, and has a soapy feel. If you add vinegar
to a dry portion, it instantly neutralizes the hydroxide to sodium
acetate and water. The equation is

CH3COOH(aq) + NaOH(aq) --> CH3COONa(aq) + H2O(l)

Of course, it should be stressed this stuff is very dangerous and
requires all the precautions for corrosive chemicals. As you know,
it will eat holes in your skin. It doesn't hurt much since it also
destroys the pain cells, but they take a long time to heal. Some
eyeglasses are made with a plastic that dissolves with NaOH. A few
drops in your eye can cause permanent blindess in seconds, so wear
protective glasses.

Good luck!

Regards,

Mike Monett

And there he says: "For the VHF-Bands (50-50.5MHz, 144-146MHz,
430-440MHz) a radiation resistance of 25-30Ohm has the best balance
for gain, back- and sidelobes, bandwidth and SWR at tenable losses."

We have come full-circle. [g]

Also, DK7ZB in describing what is clearly an unbalanced connection of
parallel lengths of coax ("Classic" match) says, "2. This line is a
simplified coaxial sleeve balun to avoid sleeve-waves on the braid of
the cable running to the station.", which it is clearly not.

What is "irrational" with my approach finding the best configuration AND
satisfying my desire for no loss 50 ohm impedance match?
It was not prejudice but "what if I succeed" approach and after over 3
months of fiddling with variety of designs in Canadian winter/spring I
managed to find solutions avoiding matching loss, that I would have to add
another director at X spacing to compensate for.
For example my 3 el. quad, 50 ohm, no matching beat 7 el. KLM Log Yagi with
balun on 2m.
If you can come up with whole bunch of better solutions, I would be glad to
learn about them.

Owen-

My friends with money used a 4-to-1 BalUn coil with their Windoms and drove them with rigs such as the DX-100 and Viking II. I think their Pi-network output stages matched a wider range of impedances than the modern solid state rigs can match, but I didn't know about that at the time. I thought the 300 Ohm TV feed-line was a close match to the antenna, and the BalUn transformed it to a nearly perfect 75 Ohms.

My current interest is two-fold. First, I was curious to know just how good the match might have been on the old antenna. Second, it would be handy to have a multi-band antenna that could be fed off-center so the feed-line didn't have to run parallel to the antenna wire before entering the shack.

I can afford a BalUn now. A little vertical radiation from the feed-line would be OK unless there was a problem with RF burns!

Points well taken.

In my "Food for thought" essay (http://eznec.com/misc/Food_for_thought.pdf) I use a voltage source in series with a resistor for most examples. Among the calculations are those showing the power dissipation in the resistor. I've used this simple circuit a number of times to illustrate various points regarding transmission line operation and the effects of traveling voltage and current waves.

People who aren't willing to accept the points being made borrow from the politicians' play book and immediately declare the source to be a "Thevenin equivalent" and therefore any calculation of source power to be invalid and meaningless. This handily diverts the discussion from the fundamental topic to something more to the attacker's liking. It can then proceed to endless arguments about the magnitude and linearity of a transmitter's output impedance, and whether or not it constitutes a "dissipationless resistance". The discussion has followed this path many times, and I'm sure will do so many times more.

The essay shows that "reflected power" is NOT absorbed or dissipated by the source resistor in my simple circuit -- which is NOT a Thevenin equivalent of a transmitter or anything else (although, as I point out, it is a reasonable model for some signal generators). What remains for the people promoting the notion of waves of average energy propagating like voltage and current waves to show is how their theories can explain the resistor dissipation in the very simple circuit I used. (How about a single equation showing the resistor dissipation as a function of "reflected power"?) Only after that is done is it necessary to begin the argument about what the output of a transmitter looks like.

I teach my students that prior to analysis of an electrical, electronic, or EM network/system one must ask and answer a critical question. The question is: Is the network/system linear, close enough to linear for engineering purposes, or not linear?

If linear, or essentially linear, one brings into play linear analysis. Thevenin equivalents, which are only equivalent as far as what they do to the outside world, are a part of linear analysis.

Most RF power amplifiers that deliver more than one or two watts are non-linear circuits. Typically, the active device conducts for only a fraction of each cycle. How else could one get DC power to RF power efficiencies of over 50 %? Great care must be taken in modeling such circuits.

A simple example: Consider a transformer fed bridge rectifier (very non-linear) that is connected to an (old fashion) series L, shunt C filter. In steady state, if L is large enough, one may model the rectifier as a series of series connected voltage sources with harmonically related frequencies (and a DC source). It is left as an exercise for the student to decide on the sizes, frequencies, and phases of the sources. (Because of the LPF properties of the LC network, one does not need many harmonics.) Then one may apply superposition (the essence of a linear process) to estimate the ripple on the load. However, the model just described is invalid if L is too small or if L is non-linear. The model is insufficient to predict the losses in the rectifier. This example is not likely to be found in current electronic texts, but we all know for whom they are written.

Techniques exist for dealing with many non-linear networks. They must be used with great care. If one holds one's nose, one might find an "equivalent" for a transmitter that suffices for describing what happens outside of the transmitter, but not inside of the transmitter. Please do not make conclusions about the "equivalent" itself. Please discriminate between linear and non-linear networks.

Thus ends the lecture. 73 Mac N8TT

Zero power dissipation in the source resistor is prima
facie evidence of "total destructive interference" in
the direction of the source as described by Hecht on
page 388 of "Optics", 4th edition. You see, optical
physicists don't have the luxury of dealing with voltages
and currents. They are forced to deal with power densities
and those irradiance equations work just as well for RF
as they do for light. The power equation describing the
dissipation in the source resistor is:

Pfor + Pref - 2*SQRT(Pfor*Pref) = zero

which is in perfect agreement with your calculations.

All,

The setup is an 8407a network analyzer with an 8412a display. The forward and reflection detectors are mini circuits ZFDC 20 - 4's. These are power detectors.

The question is: With a short stub on the detector will the open or the short represent zero phase angel?

The setup basically is working. Open and short read 180 degrees apart. A cap and an inductor are plus and 180 apart and 90 out of phase with the open and short.

Thanks - Dan

> short represent zero phase angel?

Assuming the phase angle is between the voltages:

The phase angle between Vfor and Vref at an open circuit
is zero (all the energy is in the E-field).

The phase angle between Vfor and Vref at a short circuit
is 180 degrees (all the energy is in the H-field).

Thanks.

The detectors are classified as power detectors. What effect would that
have?

If it would be the same then the open would be zero.

- Dan

2811. Log Spiral Grounds

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-19 04:52:48 UTC
From: "Sal M. Onella" <salmonella@food.poisoning.org>
Message-ID: <DGoLh.49211$Ko5.33168@newsfe08.phx>
Source record: 44427

The discussion(s) of ground planes, ground radials, etc, reminds me of an antenna design that I saw about 20 years ago, when I was helping to establish a Navy shore facility in San Diego. We needed some HF antennas and researched existing building-mounted HF antennas in the area.. The research led us to a local entrepreneur who built a few antennas and sold them to the Navy. They worked well.

The radiator was a Slinky-like coil that was raised inside a fiber tube, which I believe is the way the SteppIR tunes. To the point, the ground plane for this antenna was described to us as Log Spiral, a shape found in Nature from the curls of a conch shell up to the arms of a spiral galaxy.

At a price of $14,000 per copy, our program could not afford his antenna and we made do with a base tuned whip. It worked.

Because we never bought and installed the antenna, I've forgotten all the pertinent details of how many ground wires were involved, how long the wires were, how they were spaced, etc. I'm pretty much a blank slate. <:-(

What, if anything, do we know about the concept of a log spiral ground plane? Genius or snake oil or something in-between???

Google is no help. The closest I got was a log spiral HF antenna for NVIS operation described by L.B. Cebik, W4RNL, cited often here.

But then, that's the _antenna_, not the counterpoise. It's tempting to imagine that the dimensions of that antenna might be the dimensions for a corresponding counterpoise.

This is the direct link to the program:

http://www.zz-plan.eu/scope/scope_122_en.zip

However, it is on that page:
Version 1.22

* Changes
o Peak hold function in frequency analysis
o Signal generator allows now to generate white noise and a
frequency sweep
o Cue points are no longer written to the .wav file by the
sound recorder. The Media Player was confused by these extra data
* Program and manual of version 1.22: scope122_en (approx. 25MB)
* Deutsche Version 1.22 des Programms: scope122_ger (ca. 25MB)
* Only the Manual for Version 1.22

in the above, you would click on the "scope122_en" in the above--on that
page ...

From: Jimmie D <GFENDER@carolina.rr.com>
Message-ID: <45fe47b5$0$16990$4c368faf@roadrunner.com>
Source record: 44432

Been cleaning out the garage this weekend and came across an old attempt at build a 432Mhz helix antenna. As I remember I gave up on it because I was having trouble building the matching section which was a 11/4wl long fin that attches to the helix as it apprached the feed point. It was proving difficult for me to fabricate. I was wondering if the fin could not be attached to the counterpoise instead of the helix, adjusting the space beteen the fin and the helix to get a match.

Jimmie.

Why, so we have...

At the risk of going round again, I definitely wouldn't agree with that statement as written. However, it is valuable to point out that 28 ohms is one of those "convenient" impedances, which might otherwise have been overlooked.

>Also, DK7ZB in describing what is clearly an unbalanced connection of
>parallel lengths of coax ("Classic" match) says, "2. This line is a
>simplified coaxial sleeve balun to avoid sleeve-waves on the braid of
>the cable running to the station.", which it is clearly not.
>
Agreed. However, there is an alternative for 50MHz because the paralleled quarter-wave sections are a convenient length to be coiled up to make a small, neat choke.

I had a 3-element 50MHz beam which had been thrown together using existing gamma match parts, but it was picking up a lot of noise and crud - on surprising on thinking about it, because the coax shield, the boom and the mast were all connected together and acting as an antenna for local noise. Since the feedpoint impedance happened to be about 28 ohms, it was very easy to convert it to a fully balanced feed with a choke, and all the noise problems went away.

Thanks for the Info. We do use UHF and VHF systems as well however I
don't believe this is the problem here as turning of the transmitter
causes the IQ signals to go to close to DC. There is some ripple due
to ripplet from a switcher though we have reduced this to 5mA and a
large cap by the transmitter reduces this further. In addition the
switched is i a separate compartment to the transceiver.

Cutting the tracks at the tx module to the SMA connector and wiring coax directly seems to do the job, so I guess that the PCB package did not do a good job of calculating 50 Ohm. Mind you I think it was probably my fault I should have copied the module and tracks were on the inside surrounded by planes where as from the module to the SMA connector the tracks were on the outer layers of PCB. I assume the 50Ohms would also be affected once the board was in the metal box.

Paul.

Power is a scalar and doesn't have a phase. If phase
is required in a power equation, it is normally the
phase between the associated voltages, e.g. the phase
used in the interference term in the irradiance equation
in optics is the phase between the (visible) E-fields.
I would assume the power detector phase convention would
be the same as in optics, but I'm not absolutely sure.

I believe it's called the "Golden Ratio" based on
Fibonacci numbers and works as well as any other
ground plane including fractal ground planes. It,
like a fractal, is based on packing the most stuff
in the least amount of space. One sees the pattern
in pinecones, pineapples and sunflower seed heads.

2823. Hyper-light speed antenna (#6025810)

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-19 15:37:57 UTC
From: jimlux@earthlink.net
Message-ID: <1174318677.017864.283550@l77g2000hsb.googlegroups.com>
Source record: 44439

Re Roy's post:
One of my favorites is U.S. patent #6,025,810, "Hyper-Light_Speed Antenna" (Strom). Besides sending the signal at a speed faster than light and penetrating known RF shielding devices, a side benefit is that it can be used to accelerate plant growth. I've read many patents which are as fundamentally flawed, but this one has the advantage of being so obviously wacko that nearly anyone but the overly credulous can see from it just how little a patent really means as an indication of technical merit.

Roy Lewallen, W7EL

I am convinced that this application was intentionally filed to point up the bogosity(?) of the system. It was the claim for improving plant growth that convinced me.

In general, I agree with your contention that patents are granted unless there's some clear problem (perpetual motion), with the idea that they'll let the would-be infringer fight it out to invalidate it.

The PTO is full of good people, but grossly underfunded, and without sufficient institutional gumption to try and fight the tide of patents for the unpatentable and obvious.

Jim, W6RMK

2824. Re: Log Spiral Grounds

In my (shudder) early days on the Dark Side (11 meters) I once shaped a half wave length of house wiring into a conical spiral (roughly 30 inches high), hung it from a ceiling using a refigerator top as groundplane. I communicated well with folk in the White Rock Lake area from my Carrollton home (approx 20 miles) with a legal unaltered 4 watt transceiver. Fiddling about with antennas has always been an interest of mine.

An update, for the sake of archiving if nothing else; I made a high-pass
filter of nothing but a varicap at its lowest capacitance and now the 80
meter band is a joy listening to. I decided to try this since I noticed
that signals were much more powerful at lower frequencies, and suspected
that getting rid of those would improve my reception.

I did try various types of attenuation, but I wasn't quite happy with the
result. The high-pass filter is better. I'm going to make a low-pass
as well to put in series to see if I can improve reception further, and
look into better high-pass filters.

That would be the type that I'm talking about. I've used them and like
them. For some reason I see them as a nice compromise antenna, and
Richard doesn't. Or maybe I'm talking about this type, and Richard is
speaking of the other, "classic" Windom. But then again, I'm way out of
me league here!

The cushcraft A4S yagi I have is designed to have a 50 ohm feed.
It's not half bad for a tribander.. So I think it's possible to have
fairly decent gain and f/b with such a design.
In the manual, they claim 25 db f/b and 8.9 dbd forward gain.
Of course, the gain they claim may be a tad optimistic, but
in using it, it does seem to do ok. We won 10m fone using
at field day about 5 years ago.
I've designed many yagi's using modeling, but can't remember
how many I've done that were designed to have a 50 ohm
feed.. I think I've done a few though.
In most all cases, I design the yagi for what I want in gain and
f/b, and then worry about the matching later. The only
exception might be if I showed a very low Z, which might
add extra matching losses. If you design for max gain, the
feedpoint Z will usually be quite a bit lower than 50 ohms.
I think as long as you are no lower than 10-12 ohms or so,
the losses in matching are fairly low. An NBS yagi shows
appx 12 ohms or so, and I've never noticed any large loss in
feeding one even using a simple gamma match.
The cushcraft A4S uses no matching device at all.
You just roll up some coax for a choke, or add a 1:1 balun.
I use the choke myself..

One way is to run a single wire next to the reflector from the feedpoint to
the transmission line. If the Z0 of the helix is 120 Ohms, space the wire
from the refleector so that at that end it forms an impedance of 120 Ohms.
Space it at the coax end so the impedance is 50 Ohms. I think that
theoretically the impedance is supposed to change is some logarithmic
fashion, but linear reduction of distance works. If the reflectopr is not
solid, fasten a metal strip to it to get a smooth impedance. I can't
remember the minimum length for the conversion line; something like a
wavelength. Google helix antenna matching.

Hi Nos,

The standard antenna tuner (buy a cheap ham one, without the meters)
will do just as well and has served generations of SWLers. Better
yet, build one to suit your larger tuning range.

Source record: 44450

Cecil,

Thanks for the pointer. I split the sweep signal input and fed the analyzer with 'in phase' signals. I then set the analyzer phase to a known reading, line on the phase display. I then tested this by comparing it to short and open. It was almost identical to the short reading, less then about 4% difference.

This is being used to analyze a loaded dipole without any input network. With above setup the antenna is now reading 'inductive' which is consistent for this network.

The next step is to determine the amount of capacitance to bring the reflection to 0j at the frequency of interest. This could result in a reading of 0 or +/-180 degrees phase. If it is 0 then the impedance is less then 50 Ohms, if it is 180 then the impedance is greater the 50 Ohms.

Thanks - Dan

Does anyone know where I can get a few elements for my discone antenna ?

I bought it from Tandy(a.k.a.Radio Shack) electronics in the late 80's
but don't know the manufacturers name.

Tandy was bought by Dick Smith electronics so I can't go back and ask.

The elements are stainless steel hollow tubes;
4.80mm OD x 81cm(approx) long.

Am in Australia so local would be best.
Any ideas would be appreciated.

Boozo.

The directivity of a half wave dipole over real ground varies with height, and elevation angle. At the zenith it is omni directional, and at lower elevations it has some directivity, but nothing like a dipole in free space. Inclining the legs as in an inverted V dilutes the nulls further and so reduces directivity, less so for large included angle.

So, the combination of an inverted V and mounting low to real ground reduces directivity.

If you raise your dipole centre height, and decrease the included angle, I expect that one will offset the other's effect on the pattern to some extent.

Owen

Pardon my ignorance but how can I work out what the Z0 of an antenna is?
As you say above, "If the Z0 of the helix is 120 Ohms".

I'm not totally stupid but could never work it out.
It isn't as simple as connecting an ohm meter to it......is it ?

Boozo.

2840. Fan dipole..

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-20 01:28:44 UTC
From: merlin-7 <merlin-7@sc.rr.com>
Message-ID: <45ff2b0f$0$27105$4c368faf@roadrunner.com>
Source record: 44451

A question for you experts out there...
I currently use a fan dipole (kind of a fan anyway)

It has 3 elements off of each side from the feed point.
A 66 foot or 132 feet total length
A 33 foot or 66 feet total length
and a 16 foot or 32 feet total length.(this is before it was tuned so measurements are not exact)

The wires are spread 1 foot apart from each other, 18 inches from the feed point. (where the wires are connected to the feed point, they V out from there, to a point 18 inches from the feed point where the 1st spreader is located, placing each wire 1 foot apart)

The wires are (hung) under each other from that point, 1 foot apart over the total length of each wire with the longest wire (the 66/132) on top (the 33/66) in the middle and (16/32) on the bottom.

I used the longest wire to support the (pvc) spreaders for the wires hanging under it.

The feed point is at about 40 feet with the ends of the (66/132) at about 22 feet (the ends of the shorter wires are higher, due to the fact they end higher up the inverted V.

It has an air wound choke at the feed point fed with 50 ohm coax.

I have several questions regarding this set up.

What are the pros and cons of fan dipoles like this? I have never heard of a fan dipole with each element being hung under each other so I have no data to compare it to.

I would like to keep this set up when I move to my new QTH in a few months but raise it to 60 feet or so.
I know that an inverted V is for the most part omni directional, but what about an inverted v that is only somewhat inverted? Would that not give you a pattern more shaped like an egg?

I really do not wish to put up a wire for each band as the one I have now can run everything from 10m to 80m and even the low side of 160, right around 1.8 mhz (I havent figured that one out yet)with a tuner.

What are the pros and cons of adding more wires? (other than tuneing the wires being more of a pain)

I get very little interaction between the wires (maybe due to the fact they are spread apart so close to the feed point) or I just got lucky, hi hi

I am looking for ideas or someone that is great with an antenna program, that can tell me what my antenna is doing now and how to improve it at around 60 feet at the feed point.

It looks like my shack will be up befor my new home will be ready (solar power has its advantages) So I need to plan the antenna and the mounting points for the ends of the wires.(angle or slope) in other words, how high the ends need to be.

I plan on placeing the wires east / west broadside but would like a bit of an omni pattern to reach the east coast(NY to FL) from jacksonville NC.

Sorry for the long post but I know of a few out there that can give me some ideas that I have overlooked. It is better to plan ahead .....

Thanks
Joe

I haven't used the inverted-V formation, but I have used the
multi-band parallel dipole since I was first licensed in 1978. The
pros are that if the elements are 8" or closer (I never ran them
further apart), I get a broader bandwidth per band. (That comes in
handy on 80 & 40 meters.) you don't need a tuner for the three bands
of your choice (adding more wires means additional bands). If you are
a cw buff, the 40 meter dipole also doubles as 15 meters.

The cons are that the antenna isn't very stealth (if that is an
issue.), if you are running an amplifier, you could be radiating the
harmonics more efficiently. It could get tangled in the wind or limbs
of a tree (I had to deal with that and place spacers closer together.)

I have never noticed a difference in the Multi-Band Parallel Dipole
MBPD (just what I call it, probably not an official name) and a mono
band dipole as far as signal strength goes. I can't model one in my
program as it thinks that is one big fat wire.

>
> I would like to keep this set up when I move to my new QTH in a few months
>but raise it to 60 feet or so.

The higher the better...

>
> I really do not wish to put up a wire for each band as the one I have now
>can run everything from 10m to 80m and even the low side of 160, right
>around 1.8 mhz (I havent figured that one out yet)with a tuner.

80 should be a close double for 10 and 60 meters, 40 doubles with 15
meters and some combination of left and right wires double for the
other ward bands (I suppose - wag) unless 80 tunes for it. I don't
know about 160 as I have never tried to tune one to it.

>
>What are the pros and cons of adding more wires? (other than tuneing the

>wires being more of a pain)

Pros: instant switch to more bands without having to use tuner,

Cons: more harmonic risk, more wind load, more visible wire, more
weight, more expense.

I don't know what the radiation pattern will look like, but I suspect
it will be pretty much round. I would think, for the effort, it might
be well to put up two antennas, each with either three or four bands.
I mostly used 4 bands, each additional wire gets considerably more
difficult to deal with. I usually design them and space the wires
with PVC pipe which means I have to cut the pipe and add all the wires
at once or create a whole new antenna at the end.

Personally, I use #14 THHN wire which is coated and can be purchased
in various colors. I could choose different colors for each band if I
like. However, the noise factor during winter weather (ice, etc.) if
I keep them all insulated. I found that if I spaced the wires 8
inches apart, I get to reverse engineer the formula for adding bands.
This means I trim out the ten and 15 meter bands (I didn't use this
for ward bands) and then reverse engineer the formula...

x/F=L

x=468, F=Frequency in MHz, L=length in Feet.

L*F=x

Next, calculate with the new x for the additional band you desire to add. This will narrow your trimming down to a minimum.

Good luck, I am looking forward to reading all the replies.

While the overall percentage of errors is quite small even 1% or .01% would
still be a lot.Certainly enough to realise that one can not validate the
worthiness of on ides on the basis that it is patented.

Dear Jim (W6RMK): I have just returned from a conference where two of the speakers were senior officials of the USPTO. Among other things, they made clear that a large effort is being made to reduce what the PTO calls "errors." These measures include allowed applications being scrutinized by someone other than the examiner before being issued as a patent. While the backlog of applications increases, the fraction of examined applications that end up being issued as patents has precipitously decreased in the last few years.

About 1200 new examiners are being hired each FY with a total of somewhat over 5000 examiners. Obviously, the turnover is large with over 20% of the examiner corps being replaced each year.

In short, the USPTO has many of what they call "challenges," but they are trying to manage the challenges. That includes implementing means for reducing "errors."

Every time an "error" is patented, it seems to make it more difficult to secure a legitimate patent. Your contention that the error rate is large is not supported by facts. With a vigorous review process, in the last FY only 3.5% of approved applications were deemed to be "errors" and did not pass to issue. I am confident that the number of errors that managed to slip by is small indeed.

All that said, the USPTO is considering having interested parties comment by the internet during the prosecution of applications. This might start with applications in business-methods and computer related applications. This scheme would allow knowledgeable persons in the art to tell the PTO well in advance of allowance that the art in the application is old because of such and such. Other similar schemes are being considered.

We all realize that the Republic's balance of payments is kept from being catastrophic because of the export of intellectual property.

The process needs improvement. It is being improved. Really bad patents are becoming rare.

Warm regards, Mac N8TT

Dan, a short represents zero impedance, thus if resistance is less than Zo with zero reactance, the phase of
the reflection coefficient is 180ï¿½. Conversely, an open represents an infinite impedance, thus if the
resistance is greater than Zo, the reflection coefficient is 0ï¿½.

Jimmie, the patent office is not interested in worthiness, it is
interested in providing a service and protection in exchange
for findings to be printed for the advance of science. Obviously
they are not going to waste time on perpetual motion and at the same
time they would not invalidate an invention of earmuffs as being
trivial since 1/2 million were sold the first year of production. Now
that patent offices in different countries have joined together in a
loose sort of way changes have been made with respect to dormant
patents with claims of an idea without

acknoweledgment as to how the idea would come to fruition. Also if a claim was sufficiently fague the patent holder has to show that he was taking advantage of his claim i.e. manufacturing
facilities. The PTO have now documented all patents on a computor such that prominent adjectives and processes in a new request can be compared to prior patents with the same words quite easily which allows the PTO to ask for more intimate detailsfrom the applicant as to why his should be allowednow knowing of existing patents.So Jimmie to summarize the PTO is offering protection as a service such that the divuljence of the application will further the advance of science, so yes some patents will be considered useless in the eyes of some yet in the eyes of an entranapour it can be the source of riches. In terms of true science advances are made in little steps and not by a
significant myrical thus it is important that each step
be publicised until the ultimate is reached on behalf of the nation. The patent office by the way is a cash cow in that it generates more revenue that it costs to operate i.e a patent cost money by all aplicants which is why Crystal city is so influent with high cost buildings but at the same time the Government has control of the PTO and thus removes cash returns each year from the PTO for cancelling other government losses.

I've always had success matching a helix by running the first 1/4 turn
(starting at the feed point) parallel to the reflector and changing the
spacing between the 1/4 turn and the reflector until I get a low SWR.
If the reflector is mesh I put a piece of sheet metal on the mesh under
that 1/4 turn. It's worked every time, no fins, no 1/4 wave sections of
coax, etc. For my 432 MHz helix it ended up with about 1/4 inch
spacing, using #10 solid wire for the helix.

Hi there,

Could someone explain in simple terms (I know next to nothing about radio waves or electricity) what interference and attenuation problems might arise in the following scenario:

A remote controlled vehicle in a cable tunnel environment housing several 400 kV circuits, communicating to an operator located in a control room 5 km away.

The remote control vehicle is a monorail carriage and the information relayed back to the control room includes commands (forward/backward) and a video feed.

The reason why I am asking is because I went down such a tunnel and the chap who was in charge of operations mentionned that they had to install light reflectors to convert the radio signal into an optical signal because of signal attenuation and that there was a problem with interference with the electrical field generated by the cables.

I guess what I want to know is what is happening to that radio signal (I think it is a UHF signal) which means that they have to convert it to a light signal?

Also, can you beam a signal down a tunnel (40m below ground) which twists and turns both in the vertical and horizontal directions?

Thanks

Thats what I did yesterday sort of. I. took the piece of metal I was going to fasten to the helix and fastened it to the reflector and then adjusted the spacing for best SWR. The difference is I moved the counterpoise instead of the antenna to get the match. I do see why others have opted to put the fin on the wire. The spacing is so close doing it the ways we did that you may get arcing when using high power. If I ever build another one I will probably use copper instead of Al tubing for the antenna and solder the fin on the antenna.

Jimmie

The common to provide radio communication in a tunnel is to use a leakage coaxial cable which isn't 100% shielded and has slots along in the shielding.

You might be misunderstanding me, I didn't attach the piece of sheet
metal to the mesh as a fin but flat onto the mesh so what I ended up
with is a wire over a smooth, flat surface for a matching section.

It hasnt been long ago that I saw a disk cone antenna in the local radio shack here in the US. They are not that hard to make. Google diskcone antenna and I am sure you will find plenty of plans.

Succinctly and well stated.

Graphics of the voltage vectors (phasors) along open-circuited and high-impedance terminated transmission lines are gicen by Terman on page 91 of his 1955 opus. At the high-resistance termination point, it is seen that the incindent and reflected voltages are in-phase and thus add.

I seem to recall that this results in voltage doubling at the open circuit due to interruption of current at the open circuit which forces the magnetic field energy to be temporarily transferred to the electric field (Cecil`s conservation of energy at work). Again relying on a very old memory, I believe we called this voltage doubling the "Ferranti effect".

Best regards, Richard Harrison, KB5WZI

My 15th edition of The ARRL Antenna Book has those
phasor diagrams, Fig 8 and Fig 9, on page 24-5. Since
Walter Maxwell was a contributor, I'll bet that those
are Walt's phasor diagrams.

2856. Revisiting the Power Explanation

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-20 15:37:33 UTC
From: Walter Maxwell <walt@w2du.com>
Message-ID: <vi20031kbb1s7evd8qj9ch4i6o1l79elcm@4ax.com>
Source record: 44472

One of the issues discussed in this thread that Owen originated concerned whether or not reflected power
enters the power amp and dissipates as heat in the plates of the amp. Some of the posters apparently are
unable to appreciate that the reflected power does not cause heating of the amp, unless the reflected power
detunes the amp and the amp is left detuned from resonance, which of course is not the correct manner of
operating the amp.

In the last post of the original thread I presented the details of an experiment I performed (one of many
using the same procedure) on a Kenwood TS-830S transceiver that proves how and why reflected power in no way
causes heating of the amp when the amp is properly adjusted in the presence of the reflected power.

Usually, such a presentation as in the last post in that thread evokes a great deal of response, as for
example, Art Unwin's. So I'm somewhat surprised, and a little disappointed that my post has resulted in total
silence. Have my efforts in helping to solve the problem gone for naught?

Some would say that if "reflected power does not cause heating
of the amp", that proves that there is no power (or energy) in
the reflected waves. Those people obviously don't understand
the role of destructive and constructive interference during
the EM wave superposition process.

Yes. Andrew Corp. in the U.S.A. used to get a high price for such a special cable. 300-ohm TV twinlead is cheap and works very well too when used between a radio and a load to communicate with other 2-way radios along the twinlead route in tunnels and elsewhere.

Yoou need to find design equations for it. I think it was a function of
helix diameter and pitch. It is in either the Radio Amateurs Handbook, or
the ARRL Antenna book. Probably any book on antennas. Info should also be
available on the 'net.

You could measure the SWR. You know it is more than 50 Ohms; so, if the SWR is 3:1, that means 150 Ohms rather than 17.

In addition, Cecil, the experiment also proves that the reflected power doesn't heat the plate, because the
output source resistance is non-dissipative.

Cecil,

What reflected waves?

An equally valid description in steady state, after all the transients have died out, includes a standing wave containing the stored energy in the line plus a forward traveling wave carrying the energy that does make it through the load end of the line.

No need to account for any mythical power in the reflected waves.

This description matches your quotes from Hecht and from Ramo and Whinnery that I attached a few days ago.

I understand what happens to the direction and
momentum in the reflected wave when it encounters
an impedance discontinuity at some distance from
the source, e.g. a Z0-match.

What happens to the direction and momentum in the
reflected wave when it encounters a non-dissipative
resistance at the source?

Cecil has an IEEE dictionary which defines power in terms of the voltage and in-phase current passing a point.

Terman says on page 96 of his 1955 opus:
"The reflected wave is identical with the incident wave except that it is traveling toward the generator."

Bird says of its Model 43 RF Directional "Thruline" Wattmeter:
"The forward wave travels (and its power flows) from the source to the load. It has RF Voltage Ef and current If in phase, with Ef/If=Zo.

The reflected wave originates by reflection at the load, travels (and its power flows) from the load back to the source, and also has an RF voltage Er and current Ir in phase, with Er/Ir=Zo."

I realize this is a late posting to the question. However, the "F" connector is designed for small signal levels. The male connector does not usually make strong bond to the coax's shield. Even the center conductor if the female "F" connector does not have a strong bond. If you tried to push too much power through the connector you may create intermod or arching. Like some of the earlier posting stated there are several factors that will determine how much power can be applied. i.e. SWR, frequency, duty cycle, or cw, quality of the connector, workmanship of the connection, etc.

Talk about echoes!

Cecil, at the time of writing, you have made 4 of the 7 responses to Walt's posts, and there is nothing in what you have said that you haven't said recently.

The language from various posters like:

"Some of the posters apparently are unable..."

"Some would say..."

"people obviously don't understand..."

"How can you possibly deny..."

doesn't seem to me the language of convicing arguments, much less proof, from either side. They seem more a sign of the posters frustration, but not otherwise convincing.

My guess is that this discussion will not converge on a convincing outcome.

If the past is any indicator, just when agreement of two or three people looks likely, someone will inject some noise like lets start dealing with time domain and transient issues to prove that steady state analysis is invalid in the practical sense, or this needs a photon explanation with reference to a text no one is likely to have. It as though those posters intended to wreck logical development and conclusion. Ah, but that is USENET!

The basis of the assertion that a PA is naturally or magically conjugate matched as a necessary consequence of adjustment or design for maximum power output is based on an leveraging the Maximum Power Transfer Theorem which depends on a linear source. I don't recall seeing experimental results to convincingly demonstrate that the PA is a linear source, though I have seen those that suggest otherwise. If the source cannot be proven to be sufficiently close to a linear source, then the basis for arguing the implicit conjugate match dissolves.

No one has yet come up with a quantitative proof that in the general case PAs of all kinds have an equivalent source impedance the conjugate of their load, nor convincing experiments that would place bounds on the reflection coefficient looking into the PA for practical transmitters.

No one has demonstrated that using equivalent impedances etc is not a valid analysis of the steady state behaviour.

2869. The effect of insulation on small loops

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-20 22:22:40 UTC
From: Owen Duffy <none@no.where>
Message-ID: <Xns98FA5F61E420Cnonenowhere@61.9.191.5>
Source record: 44385

In persuit of the BPL issue, I have explored small untuned loops for field strength measurement.

Comparison of a loop calibrated to an NEC2 model to a commercial loop with traceable calibration was very encouraging.

Constructors would like to use insulated wire for such a loop, and that raises the question of the effect of insulation on the Antenna Factor.

My guess is that where the loop is small, current is uniform and the effect of a slightly different phase shift around the loop due to the insulation would be very small. That would be less so at frequencies approaching the first resonance of the loop.

My understanding is that NEC4 might provide a good estimate of the difference between insulated and uninsulated wire. I don't have NEC4 and am looking for someone who might be prepared to run a bunch of models for me in batch mode. I would supply the model decks and a batch file to run them, my volunteer would need to run the batch file and zip the output files up and mail them back to me for analysis.

My intention is to produce the same data that is plotted at http://www.vk1od.net/SmallUntunedSquareLoop/ssulNEC.htm for each loop, and to plot the dB difference vs frequency to infer some general guidance on loop sizes where conductor insulation becomes significant to Antenna Factor.

Comments / volunteers?

I have never seen the thin walled stainless tubing you refer to in metals outlets in Australia. You could try model shops... but I doubt it.

Why couldn't you just get some 3/16" stainless steel rod? It is probably a brass hub, so you could probably use 3/16" brass rod equally well.

Thanks.

No, I did not want to bury the loop.

My version of EZNEC (a pay for version) appears not to model insulation.

Owen, despite our previous discussion, I have explained many times that even though the PA source upstream of
the tank circuit is non-linear (and no one's saying it isn't), the energy storage in the tank makes the output
of the tank a linear source, no matter what the shape of the current wave form may be at the input. The output
of the tank is proved linear because the voltage/current ratio at the output is non-varying and the shape of
the voltage and current wave forms are essentially sine waves. Consequently, the output circuit can be
represented by a Thevenin source that supports both a conjugate match and the maximum power transfer theorem.

Are you now denying that the output of a PA with the routine Q of 10 to 12 is not substantially a sine wave?
If you agree that it is a sine wave, then why are you arguing that there is no basis for a conjugate match?

However, none of the responses above respond to the issue of why the reflected power does not cause heating of
the amp, which is what my treatise was all about.

> No one has demonstrated that using equivalent impedances etc
> is not a valid analysis of the steady state behaviour.

A reflection is a reflection. The reflection of a ~steady-state r-f source may produce a different perceived/effective result than if that source includes transients (modulation), but such does not negate the existence of reverse/reflected power in the steady-state case.

Decades of experience with analog broadcast TV transmission systems demonstrate that the reflected power from a mismatch at the transmit antenna produces an amplitude variation (ripple) and other effects across the r-f and demodulated video channel bandwidths that are directly related to the magnitude of the antenna mismatch and the round-trip propagation time of the transmission line between the tx and the antenna (period = 1 cycle per ~491 feet of air-dielectric line).

This is evident not only from accurate measurements made via a highly directional r-f coupler sampling forward power at the tx end of the transmission line, but also from results seen on the screen of TV sets viewing those transmissions. I suspect, Owen, that you would agree that this example originates from a "practical" system.

The r-f power supplied even by a CW source is subject to the same amount of reflected power for a given antenna mismatch, which will have an appropriate effect on system performance. Whether or not that reflected power/performance effect is important (or even recognized as existent) is the issue at hand.

EZNEC, the free version, supports insulated wire - unless you want to
bury it.

If this statement about the tank circuit being ~ a linear source is valid, does that mean that any load-reflected power that appears across the output terminals of the tx stops at the tank circuit, and never sees the non-linear, non-matching Z of the active PA?

And if so, would that also mean that such a tx would not be prone to producing r-f intermodulation components when external signals are fed back into the tx from co-sited r-f systems?

Yet experience shows that this is not the case for ~closely spaced interfering signals. The only mitigation for this for a PA with a tank circuit is the rejection of that tank circuit to those off-freq, external signals, and to the resulting IM products generated by mixing with the main tx signal in the active (and non-linear) PA stage of that tx.

And the tank has VERY low rejection to load reflections of the signal bandwidth to which it is tuned.

Also to be considered are the modern broadband (88-108MHz) FM broadcast transmitters, which have no tank circuits, but except for some designs incorporating balanced 3 dB hybrid combiners are affected by load reflections about the same as a tx with a tuned tank circuit.

Richard, my earlier treatise considers only tube-type PA's with pi-network output coupling circuits used in
the Amateur Service, such as the Kenwood TS-830S on which my measurements were made. It was not intended to
consider PA's used in the tv service. Sorry, I didn't make this distinction earlier.

>And if so, would that also mean that such a tx would not be prone to
>producing r-f intermodulation components when external signals are fed back
>into the tx from co-sited r-f systems?

This issue is irrelevant, because the signals arriving from a co-sited system would not be coherent with the
local source signals, while load-reflected signals are coherent. The destructive and constructive interference
that occurs at the output of a correctly loaded and tuned PA requires coherence of the source and reflected
waves to achieve the total re-reflection of the reflected waves back into the direction toward the load.

>Yet experience shows that this is not the case for ~closely spaced
>interfering signals. The only mitigation for this for a PA with a tank
>circuit is the rejection of that tank circuit to those off-freq, external
>signals, and to the resulting IM products generated by mixing with the main
>tx signal in the active (and non-linear) PA stage of that tx.

Again, Richard, this condition is irrelevant to the re-reflection of the waves reflected by the load, because
the relevant signals are not coherent.

>And the tank has VERY low rejection to load reflections of the signal
>bandwidth to which it is tuned.

This may be true for PAs with bandwidths wider than those occurring in ham tx. However, the destructive and
constructive interference between the reflected and source waves in a correctly loaded and tuned ham tx
results in total re-reflection of the reflected waves.

>Also to be considered are the modern broadband (88-108MHz) FM broadcast
>transmitters, which have no tank circuits, but except for some designs
>incorporating balanced 3 dB hybrid combiners are affected by load
>reflections about the same as a tx with a tuned tank circuit.

And still further, Richard, the FM transmitters you refer to above are not in the same category as those used
in tube rigs used by hams.

Incidentally, Richard, have you really reviewed the report of my TS-830S experiment?

Walt

Yes, that is correct.

Where V4 uses the NEC2 engine, is insulation modelled the same way as in
NEC4? If not, is the accuracy comparable?

Cecil,

It is interesting that you can be so precise at times and so sloppy at other times. I very carefully limited my discussion to steady state conditions, which is what everyone is already talking about in this case. You then conveniently inject modulation into the mix, completely ignoring what I said.

Do the math and show us how my comment is in error. Add the two traveling waves and see if you get the summation to be precisely a standing wave plus a residual forward traveling wave. Go back and reread your quoted references and try to figure out if anything I said is different from your gurus.

73,
Gene

Joe, you are going in the correct direction with multiple dipoles fed at the same feed point. I have used that
method successfully for many years.

I discuss this method in detail in Chapter 20 of my book Reflections--Transmission Lines and Antennas, ed 1
published by the ARRL and ed 2 published by Worldradio. Ed 3 is in publication. You can download several
Chapters, including Chapter 20, from Reflections 2 from my web page at www.w2du.com.

However, if your email address is as shown on your post, I'll email you a copy of Chapter 20.

You'll find the info concerning multiple dipoles in Sec 20.2.2, Stagger-Tuned Dipoles.

The stainless rod might be the way to go. Same as my other discone.
Have tried a couple of hobby shops but they only have aluminium and brass,
and don't have the right size.
Definitely isn't aluminium.

Only other place I can think of is Hills Industries who make TV antennae and
other products. The factory is located on South Rd, Edwardstown ??

I would've liked to get an original replacement if possible, but don't like
my chances.

Boozo.

Anything roughly the same diameter and length will do.

A piece of brazing rod threaded on the end would work just fine and is
cheap.

Off course the die to make the threads will probably be the most expensive
part if you don't have that stuff on hand, but that can probably be
solved by asking around your neighborhood and friends with a six-pack
in hand.

The EZNEC insulation modeling method is basically similar to that used by NEC-4, but different. The accuracy is comparable. Both programs (EZNEC and NEC-4) are accurate only for thin layers of material with relatively low conductivity and permittivity, i.e., like typical wire insulation. But since the typical change in effective wire length is only on the order of 3% or so, high accuracy isn't required.

I believe I recall your mentioning a multi-turn loop in an earlier posting. The insulation feature in these programs doesn't model the effect of insulation between wires, which might be an important factor for a multi-turn loop. It only models the effect of the insulation on the wire's self impedance. So use with care.

Thanks Roy.

My interest is in small single turn untuned loops loaded with 50 ohms.
IMHO, the accuracy of modelling practical multi turn loops becomes an
issue because of the distributed capacitance and possibly proximity
effect.

A small test was done recently where one of my loop designs with Antenna
Factor predicted by an NEC2 model was compared on BPL emission
measurement over a range of HF frequencies with a calibrated R&S active
loop, and the median of the difference was around 0.5dB from memory,
InterQuartileRange was less than 1dB... so that provides some confidence
that the models are sound.

I think I recall responding to someone else's post about peformance of
multiturn loops.

Roy, I went back and re-read Cebik's notes about the way in which the IS card is processed vs using and LD card to add inductive loading. He passes on an explanation:

===quote
In calculating the E-field for each segment in a model NEC calculates a "cosine" component, a "sine" component, and a "constant" component. NEC then sums the three fields to arrive at a total field value for each segment.

LD commands modify the "constant" component of the E-field calculation, whereas IS commands (in NEC-4) modify the "cosine" component. As a consequence, any workaround formulation will result in satisfying only a limited range of geometries.
===equote

It was with this in mind that I chose to head down the NEC4 path.

When I make loops (usually out of LMR400), I use my antenna analyzer to
get them to resonate properly and to match them. I really don't care
what the insulation is doing because the analyzer will tell me anyway.

BTW, a 1-turn LMR400 loop is about as good as an 80m hamstick, but a
whole lot more narrow!

But even for coherent reflections, if the PA tank circuit has very low loss for incident power (which it does), why does it not have ~ equally low loss for load reflections of that power? Such would mean that load reflections would pass through the tank to appear at the output element of the PA, where they can add to its normal power dissipation.

Also, does not the result of combining the incident and reflected waves in the tx depend in large part on the r-f phase of the reflection there relative to the r-f phase of the incident wave? And the r-f phase of the reflection is governed mostly by the number of electrical wavelengths of transmission line between the load reflection and the plane of interest/concern -- which is independent of how the tx has been tuned/loaded.

If the ham transmitter designs that your paper applies to produce a total re-reflection of reverse power seen at their output tank circuits, then there would be no particular need for "VSWR foldback" circuits to protect them. Yet I believe these circuits are fairly common in ham transmitters, aren't they? They certainly are universal in modern AM/FM/TV broadcast transmitters, and are the result of early field experience where PA tubes, tx output networks, and the transmission line between the tx and the antenna could arc over and/or melt when reflected power was sufficiently high.

For some years now, you have been arguing the reality of 'reverse power'. 'Reverse power' has served you well in that it appears to offer reasonable explanation for some phenomena:
- 'forward power' minus 'reverse power' yields transferred power
- circulators
- TV ghosting
- dissipation of pulses in generators

But there are some challenges to the premise of 'reverse power':
- where does the 'reverse power' go?
- why does the change in dissipation of a generator when 'reverse power' changes depend more on the design of the generator than on the magnitude of the 'reverse power'?

In an attempt to resolve these, you have apparently done extensive studies in optics looking for an explanation based on constructive and destructive interference but are still left with the question you posed above and others, like the one below from another of your posts:

> All one has to do to calculate the reflected power
> dissipated in the source is to understand the constructive
> and destructive interference occurring at the source
> output terminal. THIS IS EASIER SAID THAN DONE. [emphasis mine]

Like myself, others have encountered difficulties with the premise of 'reverse power'. But we have taken a different path to enlightenment than yours; we have given up on the premise that 'reverse power' represents something that is real. To do this, we have had to find alternative explanations to all the phenomena listed above, but once this was done, life was good.

I would suggest that you try trodding this path. Make a list of phenomena that you think are explained by 'reverse power'. For each phenomena, explore the possibility of alternative explanations that do not require 'reverse power'. When you have an explanation

for each, test the explanations against each other to ensure they are self-consistent, then take the body of non-'reverse power' explanations and compare it the body of 'reverse power' explanations. Which is more complete? Which violates fewer fundamentals?

You have believed in 'reverse power' for so long that you will probably find this path difficult. Make a conscious effort when thinking about circulators, for example, not to give up because it does not explain ghosting. Work out the solution to ghosting later. Similarly, when working on steady-state examples, do not confuse yourself with transients. Do those later. And when exploring a phenomena using a hypothetical generator, do not simply give up because it does not accurately model a real transmitter. Much can be learned from the simplifications of ideal voltage and current sources.

Those who have already trodden this path are, I am quite sure, willing to assist you in finding the solutions, if you are willing to learn, rather than tossing distractions into the discussion. Save the other phenomena that trouble you for a later discussion. Keep the discussion on track.

You can not lose if you take this path. In the best ending, you end up with a coherent explanation for all the phenomena and can give up on your search for solutions to the troubling issues posed by 'reverse power' and the vanishing of the energy. But even if you do not change your view you will have a better appreciation of the alternative explanations and should be better able to partake in debates on their correctness.

You could start by providing a list of phenomena for which you think the reality of 'reverse power' is the only viable explanation and offer a willingness to learn about alternative explanations.

For good reason. You feed a transmission line into an open circuit at its far end, and the power arriving at the open has no where to go but to return towards its generator. What happens at the generator upon arrival of the power reflected from the mismatched load depends on the vector values of incident and reflected waves as well as the impedance of the generator.

Searching the net for "reflected r-f power" returned over 25,000 examples. Belief in reverse power is obviously common.

You are certainly correct; many people believe in reflected power,
though I've
always found that to be a poor basis for my own beliefs.

You have also provided the classic example where the numerology works
and 'reverse power' offers a tidy explanation. I am sure this neat
example is
the basis for many people's belief.

What drove me to look at alternate explanations for these kinds of
examples
was that the 'reverse power' explanation fails miserably when the
power
gets back to the generator. Having another explanation for this
classic
example lets one let go of 'reverse power' which solves the challenges
at the
generator end. When 'reverse power' is not real, the question of where
it
goes becomes irrelevant.

Belief has nothing to do with it. Observations suffice. If you have any doubt that EM radiation can be reflected, just look in a mirror. Did you need to 'believe' you saw your reflection to confirm your observation?

> What drove me to look at alternate explanations for these kinds of

Red Herring. There is no 'failure' in the accounting of reflected power. The observations and numbers work out quite nicely.

Bird says of its Model 43 Wattmeter: "Experience using the "Thruline" Wattmeter for transmitter tune-up, antenna matching, etc. (i.e. on operating problems), shows that the power ratio is as useful in practice as the VSWR."

One can see reflected power disappear at the transmitter terminals as a match is made to the transmitter load. That eliminates stress on the transmitter from reverse power.

Reverse power is as real as its Bird Wattmeter indication.

I have yet to question the reflection of EM radiation, just the
existence of
"reverse power" in transmission lines.

> Red Herring. There is no 'failure' in the accounting of reflected power.
> The observations and numbers work out quite nicely.

A simple example that I can never make add up is a 50 Watt generator
with a 50 ohm output impedance, driving a 50 ohm line which is open at
the end. Using the "reverse power" explanation, 50 W of "forward
power"
from the generator is reflected at the open end, providing 50 W of
"reverse
power". Since the generator is matched to the line there is no
reflection
when this "reverse power" reaches the generator so it disappears into
the generator. If this is truly power, it must go somewhere else, be
dissipated, transformed into some other form or stored (based on the
conservation of energy principle). Where did it go?

Most correspondents agree that what happens depends on the design
of generator; dissipation either increases, decreases or stays the
same (compared to when the line was terminated in 50 Ohms and the
power going down the line is dissipated in the termination). This
does
not make an easy explanation for where that supposedly real power
goes. Of course, if it is not real power, then there is no issue,
which
leads one back to looking for explanations other than "reverse power".

I suggest that a more accurate description would read:
"One can see the indication on meter go to zero at the transmitter
terminals as the match is made to the transmitter load".

The scale on the meter could be labelled "furlongs per fortnight" and
this would still be true.

After exploring alternative explanations for the various phenomena,
the explorer will be ready to understand what a directional wattmeter
really measures (as opposed to what its meter scale claims to
indicate)
and truly understand what inferences can be correctly made from its
indications.

> Reverse power is as real as its Bird Wattmeter indication.

I absolutely agree with this.

I explained this last week, albeit for a different reason. I'll paste:
***
Hi Richard,
He says it in the last sentence. But here is an example. Take a 50 ohm
thevinin source. Power off, it looks like 50 ohms back into it. Take a
second thevinin source to represent a reflection and drive 5 volts into
the first source. Now set your first source 180 degrees to the
reflection and drive forward 5 volts.

(s)-----/\/\/\--------(c)-----/\/\/\--------(r)

(s)source (c)connection (r)reflection. With (s) 180 degrees out of phase
from (r), (r) will see a short at (c). It is because of the power
generated at the source that the impedance into it can look purely
reactive. And, you can use 5 ohms with 1 volt at the source, (c) will
still look like a short to (r). The source resistance doesn't matter as

long as a 'match' is made.

And for the same reason, why the 50 ohm line doesn't look like 50 ohms
is because of reflected power. Drive an open quarter wave line and it
looks like a short because the reflected voltage is 180 degrees out from
the source.
***

> If this is truly power, it must go somewhere else, be
> dissipated, transformed into some other form or stored (based on the

The energy is sitting on the line. It didn't disappear. See all the
posts I made last week.

>
> Most correspondents agree that what happens depends on the design
> of generator;

Actually, it doesn't. The exception is minor and pointed out in the case
of a non linear source.

Then, you have never matched with a reflection. Without the experience,
how can you make a claim? You have not made the observation yet you
claim what it 'should' be.

Keith,

I drafted an article exploring the operation of a Breune type directional wattmeter, it is at http://www.vk1od.net/VSWR/VSWRMeter.htm . The Bird 43 responds in the same way, but from a different sampler construction.

The article gives a simple derivation of the meter response, and deals with the legitimacy of scaling the instrument in Watts.

If one takes measurements with the instrument, it is true that the power at a point is "forward power" less "reflected power", and the manufacturer has scaled the instrument in Watts to facilitate that calculation, but that does not imply that the value of "forward power" or "reflected power" has any stand alone value, the ratio of the two is meaningful, the difference of the two is meaningful, but one alone is meaningless.

To illustrate the lack of stand-alone value of the "forward power" reading, one could place two such instruments, one calibrated for 50 ohm and another calibrated for 100 ohm in tandem at the tx, and then a load. The two instruments will indicate different "forward power" and different "reflected power".

Notwithstanding the fact that the "forward power" and "reflected power" readings are each not of stand alone, the difference between "forward power" and "reflected power" has meaning and will be the same for each instrument.

I agree with you that a lack of understanding of the instrument can be used to prop up bogus explanations and concepts, even leading to people citing the Bird 43 user manual like it was a respected and authoritative text.

I may have misunderstood, but I thought that when Richard said "see
reflected power disappear" he was observing the Bird Wattmeter
mentioned
in his previous paragraph and watching its indication go to zero. If
this
is not what was meant, then I need elaboration.

Otherwise, I think I said the same as Richard in different (and,
arguably
more precise) words.

Would any poster in this thread who doesn't "believe in" reflected power kindly explain how a transmission line can fail upstream of a serious mismatch anywhere along the the length of that line. If that doesn't result from the sum of forward and reflected voltage/current, then (IYO) what is the reason such failures?

Don't think that this doesn't occur. I've seen it many times, and had to find and replace the molten and arced-over components that resulted.

Roy,

My comment is not intended to impune EZNEC in any way. I don't know how EZNEC v4 models insulation, and cannot comment on it.

I have read a description on Cebik's page about modelling the effects of insulation by loading all segments with a constant value of L which apparently makes a insulated wire half wave dipole model in NEC2 calibrate well with NEC4' IS model. It would seem that the amount of the inductance was chosen empirically, a curve was fitted to the experimental model data. It occurs to me that the results depend to an extent on the current distribution on the conductor, and might be different for a small loop where the current is almost uniform.

The reason for the study is to be prepared to fend off criticism from opponents (the BPL industry, the FCC etc) who might criticise performance modelled on bare wire when everyone wants to make the loops from insulated wire. I can defend a NEC4 IS model, but if there are questions about the accuracy of LD loading of a small loop based on empirical data from half wave dipoles, I am in a weaker position and possibly worse than NEC2 models of bare wire.

Modelling the insulation is probably splitting hairs. If I address that, the next question will be over using stranded wire vs single core.

My mistake. You both said something that is not what happens. I will assume you are looking for no reflection between a transmitter and a transmatch. But the source to a transmission line is on the other side of that transmatch. You will most certainly see a reflected wave if the end of that transmission line is not terminated into purely 50 ohm load.

> Otherwise, I think I said the same as Richard in different (and,
> arguably
> more precise) words.

I see that. But neither is the case. If you are matching a transmitter to mis-matched line, the reflection does not go to zero. In fact, the reflection is a function of the line and termination and is constant. Nothing you do at the transmitter can change it.

Without making any admissions about my beliefs...

A transmission line with mismatched load can be described in terms of
travelling waves, and the voltage and current at a point on the line can
be calculated from the forward and reflected waves.

The voltage at the point may be higher than under matched conditions for
the same load power, and that may cause insulation breakdown.

The current at the point may be higher than under matched conditions for
the same load power, and that would cause higher loss in conductors and
may result in damage.

> Don't think that this doesn't occur. I've seen it many times, and had
> to find and replace the molten and arced-over components that

None of these explanations require designating "reflected power" at a
point, or implying that it is the energy in "reflected power" that is
totally and solely responsible for the physical damage.

Dealing firstly with wire of uniform material (ie unclad), you propose to anneal the wire, which at least reduces its strength, changes its elasticity, and may affect its corrosion properties.

In the case of copper clad wire, you may upset the bond between copper and steel core or induce cracking in the copper cladding, either during the heating / cooling process or in service due to the changed elasticity of the core.

I wouldn't even think of it.

Wear safety goggles, and be very careful with the springy wire. Or, use soft copper and replace it if / when it blows down.

An underlying assumption in any NEC model is that the current in any given segment varies only a small amount from one end to the other. Therefore, any criteria applicable to a loop should also apply to other geometries. If not, then the other geometry has an insufficient number of segments. I would, however, use NEC-4 if in your shoes, because the source code is available for scrutiny. Be careful, though, since there have been quite a few modifications to NEC-4 since its introduction, and various compilations can also give slightly different results. None of the changes have been in the insulated wire calculation that I'm aware of, however.

It is indeed splitting hairs. The effect will be so small it will be hard to see in a model (except possibly in the resonance of a very high Q loop) and probably impossible to discern by measurement of a real loop. But then your modeling and measurements will show you that.

Stranded wire might noticeably reduce the Q of a very high Q loop, but I couldn't be sure. Its effect can be seen in coaxial cable, but the field distribution around the center conductor is very different than for an antenna wire.

it.hi hi
I have not looked at the file in detail but from what I saw it looks great.
I did not see the distance in spaceing the elements apart in there and what
effect that has (I may have overlooked it)

I like fan dipoles and have no problem hanging a 5 wire one (this time I
will measure every wire after there all tuned) just in case I need to
replace it. Tree limb, ice. etc.
I forget the name of the copper clad steel I have for the new shack, but
its the large gauge and hard to work with but should work well and stay up a
long time after I finnish cussing.

Like I said, I hang the longest wire on top and the shortest on the bottom
(under each other)

I may need to use copper strand for the shorter wires to keep from ending
up with a giant slinky.

I also use (weed eater line) from the bottom of some of the spreaders to a
point below where the ends of the dipole are tied off to keep the whole
thing from twisting up in bad weather. The short one just has a weight under
it.

Sound good?

Now, I just need to figure out the spaceing between elements. At 12 inches
I get very little interaction but someone posted, If they were closer, The
bandwith would be wider.
I am trying to preplan as much of this as I can. I do not mind climbing a
tower but the less trips I have to make the better (damn I wish I did this
when I was 20) hi hi

Some of you may have read my posts on the parallel dipole. I have some large gauge copper clad wire. It has a memory and is a pain to work with but it has a breaking point of around 800lbs (I think that's right)
Can you stretch that stuff out tight and take a propane torch to it so that it will not slinky on you? Without damaging it?

Thanks

You pose a phonomenon that should be added to the list that
needs to be explained without the use of "reverse power".

And you have done an excellent job of doing so by providing
an explanation that refers only to forward and reflected
voltage and current. Not a mention of "reverse power" in
the explanation..

I guess you are relying on the fact that there will be no reflected r-f voltage/
current if there is no incident voltage/current? And no argument, there.

But of course, it is the vector sum of ALL of these that may cause the transmission line/network/tx failure(s) mentioned in my relevant posts in this thread.

And so that does NOT prove that reflected power/voltage/current does not exist, or is unimportant in an r-f system design.

The specifications of a transmission line or other r-f network or circuit can be chosen with due engineering care to be rated for a defined incident power applied to a load with a given mismatch to a specific Zo, and with respect to the carrier frequency, the modulation thereon, the ambient air temperature/pressure, solar illumination, line pressurization, and other operating parameters.

These realities are commonly recogniz(s)ed and incorporated by most commercial designers/evaluators of r-f transmission systems, and as a result pose no significant problems to them and/or their clients.

But none of this means that r-f reflections do not, may not, or can not exist -- whether in "ham" systems, or otherwise.

I agree with what you say.

I had made the leap that Richard's configuration was transmitter,
Bird, matching
device as that seemed to be the only way that an adjustment could
bring
the meter on the Bird to zero. If this was not the intended
configuration
then I am completely confused and Richard will need to clarify his
intent.

When I was a kid my grandfather ran a depot for the G&F railroad and I
remember them replaceing some of the telegraph lines there. They drew
the wire through a device that had rollers in it to take out the curl.
I dont really remember how it worked but that it was pretty simple. Im
betting it was probably much like those 3 roller devices you use to
put curl in metal rods.

Negative assertions are usually impossible to prove.
The onus of proof is upon the ones who assert that
reflected waves cease to exist during steady-state.
The distributed network reflection model has yielded
valid results for a century or so. Ramo and Whinnery
go so far as to talk about the forward power flow
vector and the reflected power flow vector. People
trying to discredit that model just haven't accomplished
their goal.

Every real world system has noise modulation
that can be tracked through the system riding on
the forward and reflected traveling waves. Thus
steady-state is never reached in reality and your
argument is therefore just a mind game.

Nope, for the last few years I have been arguing the
reality of a reverse or reflected EM energy wave. Energy
is what moves and is the essence of an EM wave moving
at the speed of light. All I am arguing is the validity
of the distributed network reflection model, something
that has stood the test of time for a century or so.

Reflected energy waves obey the principles of conservation
of energy and superposition some of which is discussed in
my WorldRadio energy article at:

http://www.w5dxp.com/energy.htm

> I would suggest that you try trodding this path. Make a list of
> phenomena that you think are explained by 'reverse power'.

Actually, "reflected energy" rather than "reverse power".
Here is very close to an experiment we did at Texas A&M
during the 50's. We observed the ghosting and the professor
explained reflected energy waves to us.

TVSG-----1000 feet 450 ohm ladder-line---75 ohm TV RCVR

If the TV Signal Generator is not equipped with a circulator
to get rid of the reflected energy wave, ghosts will appear on
the TV RCVR. The ghosts are exactly where they should be if
reflected wave energy exists. How would you explain the
ghosting?

Please see above. And please abandon the words, "reverse
power" in favor of reverse or reflected EM energy wave.

Oh yeah, I forgot to tell Keith that I'm not the only
one who believes in the validity of reflected energy.
In fact, I see it every time I look in the mirror.

Also HP Ap Note 95-1 has some interesting things to
say, e.g. "|a2|^2 = Power reflected from the load."

The reverse energy wave follows the principles of
conservation of energy and superposition. That we
have no clue what the generator looks like to the
reflected energy wave is not a good reason to
abandon those principles. In fact, allowing
destructive interference to be accompanied by
an energy reflection solves all the problems.

This is a lot like the 1/2WL W7EL example in his food for
thought articles. The generator is *NOT* matched to the line
as it sees an open circuit and cannot continue to stuff 50
watts into the open circuit. The generator is as mismatched
as it can possibly be. The reflected wave also sees that open
circuit and is 100% reflected. Since the generator is not
delivering any power and there is a forward power and a
reflected power, the reflected power is supplying the
forward power. Anything else violates the conservation
of energy principle.

> Most correspondents agree that what happens depends on the design

Any level of interference is possible depending upon the
phase angle between the forward E-field and the reflected
E-field. All this is explained in "Optics" by Hecht which
some people have apparently avoided reading/understanding.
Optical physicists solved this problem a century ago. They
don't have the luxury of dealing with voltages and currents

and are forced to deal with power densities. You should
try trodding their paths and enlightening yourself.

How do you explain the fact that a transmission line
contains exactly the amount of energy needed to support
the actual forward power and reflected power? If it
is not moving at the speed of light (modified by VF)
it is not EM energy.

EM wave energy necessarily travels at the speed of light.
There is exactly the amount of EM wave energy contained
in a transmission line to support the forward power and
reflected power.

The forward voltage is in phase with the forward current.
The reflected voltage is in phase with the reflected
current. Vref*Iref*cos(0) = reflected power

You are not suggesting that the energy contained in a transmission line in the steady state in the general case is constant, are you?

Cecil, every time someone *almost* succeeds in making you stick to the point, you accuse them of messing with your mind.

Nobody is trying to restrict your freedom of thought or speech. Nobody wants to, and nobody can. But lots of people are hoping, begging, pleading that you develop the SELF-discipline to follow an argument all the way through to its conclusion, without jumping outside of the boundaries you laid down at the start.

This may indeed trouble your mind; but the process of scientific inquiry wasn't ever *intended* to feel comfortable. Its only goal is to find things out and get them right... and that involves staying on track, even when it takes you outside of the comfort zone. In fact, then most of all, because it's a sure sign that the track is leading somewhere.

> the steady state in the general case is constant, are you?

Obviously, a leading question. :-) I'm not talking
about instantaneous values here. All my statements
apply only to values averaged over an integer
number of RF cycles in one second.

What I am saying
is that a transmission line obeys the conservation
of energy principle. Whatever energy has not gone
somewhere else is still in the transmission line
and is exactly the sum of the energy required by the
forward wave plus the energy required by the reflected
wave. The steady-state energy stored in a transmission
line with reflections is greater than the steady-
state energy delivered to the load. The extra energy
was sourced during the transient build-up state and
has not yet been delivered to the load. The argument
that 100 watts in and 100 watts out (during steady-
state) doesn't leave any energy left over for the
reflected waves is invalid. Below I give an example
of 100 watts in and 100 watts out with 300 joules
stored in the forward and reflected waves.

I think it would be safe to say that for any one-
wavelength section of line, the average energy
content is constant during steady-state and is
exactly the amount of energy required to support
the forward traveling wave and reflected traveling
wave.

Here's a graphic that I earlier provided that
illustrates the energy buildup to steady-state.

Sorry Ian, I don't trust you guys enough to roll
dice in the dark with you and then let you tell
me what value was rolled. :-) You are perfectly
free to play mashed potatoes with RF joules but
please don't ask me to join in. Sometimes I think
you have to be just pulling my leg.

It was Gene who first pointed out the difference
between a traveling wave and a standing wave. Now
he says there is no difference.

> Gene Fuller, W4SZ wrote:

>> seen again.

One can send two coherent light beams in opposite
directions almost collinear to each other and observe
the standing waves. Hecht has a graphic of such in
"Optics". The two light beams, forward and reverse,
emerge past the standing wave space undisturbed and
unaffected by the superposition.

How does your theory hold up when measurement of voltage
and current is impossible and everything occurs in free
space for anyone to observe with his/her own eyes? If it
doesn't work for EM light waves then it also doesn't
work for EM RF waves except as a shortcut.

So please take the above example from optics and show
me how the reverse traveling wave is different on
either side of the standing wave space.

Richard, your statement above begs the question, "Are you aware of the phase relationships between forward and
reflected voltages and between forward and reflected currrents that accomplish the impedance-matching effect
at matching points such as with stub matching and also with antenna tuners?

When the matching is accomplished the phase relationship between the foward and reflected voltages can become
either 0ï¿½ or 180ï¿½, resulting in a total re-reflection of the voltage. If the resultant voltage is 0ï¿½, then the
resultant current is 180ï¿½, thus voltage sees a virtual open circuit and the current sees a virtual short
circuit. The result is that the reflected voltage and current are totally re-reflected IN PHASE with the
source voltage and current. This is the reason the forward power in the line is greater than the source power
when the line is mismatched at the load, but where the matching device has re-reflected the reflected waves.

This phenomenon occurs in all tube transmitters in the ham world when the tank circuit is adjusted for
delivering all available power at a given drive level. When this condition occurs the adjustment of the
pi-network has caused the relationship between the forward and reflected voltages to be either 0ï¿½ or 180ï¿½ and
vice versa for currents, as explained above. When this condition occurs, destructive interference between the
forward and reflected voltages, as well as between the forward and reflected currents, causes the reflected
voltage and current to cancel. However, due to the conservation of energy, the reflected voltage and current
cannot just disappear, so the resulting constructive interference following immediately, causes the reflected
voltage and current to be reversed in direction, now going in the foward direction along with and in phase
with the forward voltage and current.

In transmitters with tubes and a pi-network output coupling circuit there is no 'fold back' circuitry to
protect the amp, because none is needed, due to the total re-reflection of the reflected power. It is only in
solid-state transmitters that have no circuitry to achieve destructive and constructive interference that
requires fold back to protect the output transistors.

This has been a quick and dirty explanation of the phase relations that accomplish impedance matching.
However, I have explained it in much more detail in my book "Reflections--Transmission Lines and Antennas."
Yes, I know the book has been sold out and now unavailable, but I have put several chapters on my web page
avaliable for downloading. The pertinent chapters covering this issue are Chapters 3, 4, and 23, available at
www.w2du.com. I hope that reviewing these chapters will be helpful in clearing up some of the
misunderstandings that are clearly evident in some of the postings on this thread.

One can illustrate the destructive and constructive
interference with a solid-state transmitter and
no tuner. Consider the following example using
S-parameter terms.

100W--50 ohm line--+--1/2WL 300 ohm line--50 ohms
a1--> <--a2
<--b1 b2-->

Since there is zero reflected power on the 50 ohm
line, we know that "total destructive interference"
(as described by Hecht in "Optics", 4th edition, page
388) exists toward the source at point '+'.
s11 = (300-50)/(300+50) = 0.7143 = -s12
b1 = (s11)(a1) + (s12)(a2) = 0

Note that given a1, s11, and s12, we can calculate the
magnitude and phase of a2 needed to make b1=0. That
is the Z0-match condition.

The conservation of energy principle says that, (in
a transmission line with only two directions) "total
constructive interference" must exist in the opposite
direction to the "total destructive interference" and
that they must be of equal magnitudes. That tells us
what *must* happen to the energy associated with the
a2 reflected wave.

All of the energy incident upon point '+' from both
directions, |a1|^2 + |a2|^2, is directed toward the
load by the interference patterns at the Z0-match
point '+'. We hams commonly refer to that condition
as being 100% re-reflected.

The above is true in the special case of a Z0-match.
In general, |a1|^2 + |a2|^2 = |b1|^2 + |b2|^2
and since |b1|^2 = 0, the above expression is
correct.

Quoting from HP Ap Note 95-1:

|a1|^2 = Power incident on the input of the network
(i.e. Forward power on the 50 ohm line)

|a2|^2 = Power reflected from the load
(i.e. Reflected power on the 300 ohm line)

|b1|^2 = Power reflected from the input port of the network
(i.e. Reflected power on the 50 ohm line)

|b2|^2 = Power incident on the load
(i.e. Forward power on the 300 ohm line)

end quote from HP Ap Note 95-1

Cecil,

I see you are back to using S parameters to disguise the fact you are using
about Vf and Vr in trying to support your "power wave" explanation of what
happens on the transmission line.

S parameters are ratios of Vf and Vr.

Owen

This gets confusing. You are talking about "the amount of EM wave energy contained in a transmission line" and now you qualify it with "values averaged over an integer number of RF cycles in one second". Average energy over time is POWER... are you talking about power and foxing us by calling it energy. I am confused.

Cecil,

Utter nonsense. I have never said any such thing.

What I *did* say, and it is still true today, is that there is no difference between a standing wave and its *constituent* traveling wave components. It is purely a matter of mathematical convenience. There is no underlying hidden physics available from trying to look at only one of the traveling wave components. If you sort out an individual component then the standing wave is no longer there.

<ad hominem> Your debating style is a bit rough, but it is clear from this thread that others have observed your tricks. </ad hominem>

Others use the term "power wave", Owen, but *I DO NOT*
so please stop accusing me of something of which I am
not guilty. I use the term "EM RF energy wave" for
the traveling waves under discussion.

When anyone can prove that RF energy waves don't exist
or are not associated with EM energy or don't move at
the speed of light, I will retire from the argument.
Good luck on that one.

> S parameters are ratios of Vf and Vr.

Exactly! No disguise intended - it's just additional
support from the well respected field of S-parameter
analysis for the distributed network wave reflection
model. The only difference is that the S-parameter
Vf and Vr values are normalized to Z0 so when they
are squared they indeed do yield watts.

Your tone seems to reject the S-Parameter analysis
as a valid model of reality. Any model that has to
resort to rejecting the S-Parameter analysis as well
as the distributed network wave reflection model is
certainly suspect. Did you ever see the movie, "One
Bridge Too Far"? This "reflected wave energy doesn't
exist" argument reminds me of that movie.

I have been convinced by Jim, AC6XG, to abandon the word
"power" because of the difference in definitions between
the field of physics and the field of RF engineering.

Jim would argue with you and say that average energy over
time is NOT necessarily POWER and is only power if actual
work is done which, of course, is not done by a reflected
wave.

So you need to go off and argue with Jim over the
definition of "power". Instead of talking about power,
Jim has convinced me to talk about watts or joules/sec
which he says are not necessarily power. The confusion
comes from the field of physics, not from me. While you
are talking to Jim, get him to explain the definition
of "transfer".

Not at all.

S parameters are Vf and Vr based and when properly applied will produce exactly the same analysis outcome.

It is the application of S parameters in the "power flow analysis" that is a reach, it might be convenient, but it does not legitmise the argument that forward and reflected "power waves" exist separately.

A quote from HP (which you seem to respect):

===quote
Notice that the square of the magnitude of these
new variables has the dimension of power. |a1|^2
can then be thought of as the incident power on
port one; |b1|^2 as power reflected from port one.
These new waves can be called traveling power
waves rather than traveling voltage waves.
Throughout this seminar, we will simply refer to
these waves as traveling waves.
===equote

There is a difference between "can then be thought of as..." and "are...".

Gene, W4SZ wrote:
"No need to account for any mythical power in the reflected waves."

My dictionary defines reflected power as:
"The power flowing back to the generator from the load."

Maximum power theorem is defined as:
"The maximum power will be absorbed by one network from another joined to it at two terminals, when the impedance of the receiving network is varied, if the impedances (looking into the two networks at the junction) are conjugates of each other."

Clearly a generator (transmitter) connected to a load through a lossless line sees Zo of the line as its load until the instant that reflected power returns to the generator from the load.
Suppose the round-trip delay of the line makes the reflected voltage exactly in phase with the transmitter output. further suppose the reflection was total so that the reflected voltage exactly equals the transmitter output. In this special case, we might as well be connecting identical battery cells in parallel. No current is going to flow. The generator is seeing infinite impedance.

What is the generator load that extracts maximum power from a transmitter? A conjugately matched load, of course. To determine the impedance of a transmitter, one only needs to find the load which extracts maximum power. The transmitter impedance is its conjugate.

Best regards, Richard Harrison, KB5WZI

A neat diversion from the issue re the "amount of energy" qualified later as a average over time which is a different quantity, Joules vs Watts to many of us.

The fact is that the energy stored in a transmission line in the steady state is in the general case, a time variable, and you cannot state the energy (in joules) at a point in time knowing only forward and reflected power and the one way propagation time.

So Cecil,

Is it all about semantics? Is the lack of a shared language the cause of difficulty understanding your concepts. You wouldn't be alone, Art experiences the same difficulties with convention.

Hi Walt,

It is not irrelevant, merely illustrative of the concept of reflection
that is consistent with a coherent source.

Your points of phase are the sine non quo to the discussion, but all
too often arguers only take the half of the 360 degrees available to
argue a total solution. Even more often, they take only one or two
degrees of the 360.

>>But even for coherent reflections, if the PA tank circuit has very low loss
>>for incident power (which it does), why does it not have ~ equally low loss
>>for load reflections of that power? Such would mean that load reflections
>>would pass through the tank to appear at the output element of the PA, where
>>they can add to its normal power dissipation.

This is the symmetry of the illustration of external signals. You
used external signals yourself as part of your case study; hence the
relevance has been made by you.

>>Also, does not the result of combining the incident and reflected waves in
>>the tx depend in large part on the r-f phase of the reflection there

It seems he is on the face of it, doesn't it? Afterall, he is quite
explicit to this in the statement you are challenging.

>When the matching is accomplished the phase relationship between the foward and reflected voltages can become
>either 0ï¿½ or 180ï¿½, resulting in a total re-reflection of the voltage. If the resultant voltage is 0ï¿½, then the
>resultant current is 180ï¿½, thus voltage sees a virtual open circuit and the current sees a virtual short
>circuit. The result is that the reflected voltage and current are totally re-reflected IN PHASE with the
>source voltage and current. This is the reason the forward power in the line is greater than the source power
>when the line is mismatched at the load, but where the matching device has re-reflected the reflected waves.

Nothing here contradicts anything either of you have to say.

>This phenomenon occurs in all tube transmitters in the ham world when the tank circuit is adjusted for
>delivering all available power at a given drive level.

This introduces the two concepts of the "need for match" and the
"match obtained." They are related only through an action that spans
from one condition to the other. They do not describe the same
condition, otherwise no one would ever need to perform the match:

>When this condition occurs the adjustment of the
>pi-network has caused the relationship between the forward and reflected voltages to be either 0ï¿½ or 180ï¿½ and
>vice versa for currents, as explained above. When this condition occurs, destructive interference between the
>forward and reflected voltages, as well as between the forward and reflected currents, causes the reflected
>voltage and current to cancel. However, due to the conservation of energy, the reflected voltage and current

>cannot just disappear, so the resulting constructive interference following immediately, causes the reflected
>voltage and current to be reversed in direction, now going in the foward direction along with and in phase
>with the forward voltage and current.

If a tree were to fall onto the antenna, a new mismatch would occur. Would the transmitter faithfully meet the expectations of the Ham unaware of the accident? No, reflected (0-179 degrees) energy would undoubtedly offer a 50% chance of excitement in the shack. The consequences of dissipation would be quite evident on that occasion. For the other 180 (180-359) degrees of benign combination; then perhaps not.

>In transmitters with tubes and a pi-network output coupling circuit there is no 'fold back' circuitry to
>protect the amp, because none is needed, due to the total re-reflection of the reflected power.

That would more probably be due to cost averse buying habits of the Amateur community, and the explicit assumption of risk by them to react appropriately in the face of mismatch. Tubes were far more resilient to these incidents than transistors of yore.

>It is only in
>solid-state transmitters that have no circuitry to achieve destructive and constructive interference that
>requires fold back to protect the output transistors.

They too have access to the services of a transmatch that is probably more flexible than the tubes' final. If they didn't use a tuner, then the foldback would render many opportunistic antennas as useless. Again, as a cost item, this solution (fold-back) is dirt cheap and was driven by the market economies of a more onerous and costly repair through a lengthy bench time to replace the transistor (which has an exceedingly high probability of a quicker failure for a poor job).

I have been searching the internet, it seems to me someone would have:

1) Constructed an airtight room, filled it with a gas such as neon and placed an antenna in such a room. The power/freq to the antenna could be varied and "patterns" observed in how the rf was exciting the gas into "glowing" in the visible range while observing any visible patterns in such.

2) Constructed gas insulated coax enclosed in a glass or plastic tube with sufficient gap in the outer conductor where observations could be made to see if "reflections" or other observable anomalies, and voltage and current observed.

Anyone aware of anything close to any of this. Seems like this is right up some universitys' alley, nasa, etc. ...

The time-averaged energy stored in a transmission line
doesn't vary with time (by definition) unless something
changes.

If the forward and reflected powers are based on fixed
RMS values of voltage and current with fixed sources and
loads, then certainly, time-averaged energy values can be
calculated. That's the nature of *irradiance* in optics
where instantaneous values are impossible to measure. The
Power Flow Vector is analogous to irradiance.

> Is it all about semantics? Is the lack of a shared language the cause of

No, the basic problem is that you keep accusing me of
saying something I never said. I have never used the
term "power wave" except in postings like this one.
I have no idea what is the definition of "power wave".

How it feels:

It feels to me like you are one of a number of people
willing to reject the basic principles of physics in
order to mount an argument with me or anyone else
who have been convinced by those laws of physics that
reflected energy waves exist in reality - you know,
the ones you actually see when looking in a mirror?

Been done already, it is called a slotted line, and it is one of the
methods of direct measurement of VSWR. Not only did it allow direct
measurement of VSWR, but the position of the pattern could be observed, and
located wrt a known mismatch (typically a s/c) at the load plane. thus
allowing calculation of the complex load impedance.

Back in 1974 I used to visit an amateur radio repair shop in Jacksonville FL, it was located on Pearl, ave or st, cant remeber which near 8th street. I remember that quite a few hams would come into the place and often conversations about different aspects of ham radio would get started. One day they were discussing the Windom antenna with both praise and damnation. At the end(3hrs or so) at least I had deciced the the antennas greatest claim to fame was that it would load up on all the HF bands with at least mediocre performance, Probably not a bad antenna if you could only have one antenna. I do remember that someone working out current distribution in the antenna and claimed that on some bands the current was distrubted primarily in the vertical and the short section of the horizontal and in othe current was in the vertical and the long section of the horizontal section for other freqencies. I look back on this with a certain amount of aw(assuming he was reasoably correct in his computations) that this was performed with pencil and paper bag and not with aid of a computer.

2954. New General with dipole questions

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-22 22:02:51 UTC
From: garlicman <None>
Message-ID: <48KdnUkL-73rip7bnZ2dnUVZ_qyjnZ2d@comcast.com>
Source record: 44229

I just passed my General exam a week ago. I've got a Yaesu FT-990 and made a 40m dipole with some 12g wire (each side about 33 feet long). I got it outside along the roof with part drooping off the roof. I intend to suspend it between the chimney and a tree when the universe comes together so that I am off work, it stops raining, and I get over this cold.

I haven't transmitted yet, but I noticed a couple of things listening to the bands:

1. Lots and lots of noise.
2. 80m comes in quite well.

Will getting the antenna higher reduce the noise? How do you account for the good 80m reception?

John Smith I wrote:

[...]

I hear, "Been there, done that."

However, Cecil has made the comparison of optics and RF (well, he has been the most vocal on the subject), and I do NOT dispute that there are similarities, indeed, they may well be "one and the same." I am neither a believer that they are, nor do I favor that they are not ... the fact that rf behaves both as a wave and as "photons" is NOT denied ... but, a 20,000 cycle freq can be generated by, both, a musical instrument and a vlf osc ... one can be received by the ear, the other cannot, the other can be received by a receiver, the other cannot ... (and yes, I do understand about "air vibrations" and the vibrations in the EM spectrum!--and that the two spectrums' overlap!)

However, we have not really "seen" how rf is "launched" forth from our antennas--how it interfaces with "nothing" (or, ether) or is escaping as bundles of photons ...

I understand the use of field strength meters, gauss meters, etc. But still, it is not the same as "seeing." An example might be a light meter(s)/thermometer(s) in a room telling me about a light source--but it isn't quite the same as opening the door of that room and viewing the light source directly, to walk the room with mirror, prism, polarizer, magnifier, etc. in hand.

I have even went and purchased thousands of surplus neon bulbs and strung them on mono-filament lines about an antenna, placed neon bulbs from them and made observations on 1W-1KW+ of power to a monopole (the energy of youth is better expended that way--I mean, it beats hanging out in bars!--but then girls took over :-P) I always wished I had that roomful of neon (or other excitable gas.) I have taped the neons to coax and observed the flow of rf on the outer connector ...

I have seen a large neon bulb in a microwave and the patterns formed in the gas ... and it only left me dreaming of the "neon room" and full sized antennas in such ... (yes, vhf-uhf-shf if you can't afford a BIG room.)

I would just like to view what I proposed in the original post to this thread, good definition pics would suffice ... yanno, a pic is worth a thousand words ... perhaps it has been done in another country?

Oh well, one has to have something to think about ... I really have a hard time believing (taking a "leap of faith") until I have actually

seen something, it is like that for me--but then, you already knew that
... bad as that is, I am quite comfortable with it ...

Warmest regards,
JS

Great deduction, Owen! Perhaps Art would benefit from a copy
of "Gaussian Optics, with Definitions". Thinkiing about that makes
me wonder....if Cecil were to feed a one-second long transmission
line, 50 Zo, terminated by Art's Gaussian Array, how long before
the (power)(energy)(whatever) starts sloshing ??

That's the problem that the "zero energy in reflected
waves" crowd have. If they admit they can see themselves
in a mirror, they have defeated their own argument. So
they must necessarily close their eyes and deny reality.

Look up Lecher Lines... Essentially the same idea.

One can also see the evidence of breakdown after the fact, by, e.g.
melted spots in coax.

Another interesting experiment is to take a plate full of marshmallows,
closely packed, and put it into a microwave oven (without the rotating
table turning)..

The mode pattern (standing waves) will be melted into the marshmallows.

As a matter of inquiry, "You ever pointed a video cam at a mirror at the end of a hallway and seen the infinite reflections?" Quite an interesting effect, an experiment worth doing (well, it impressed me--but then, you know that don't take much :-( )... you might remember having seen it done as a special effect in movies before? Perhaps the web has an example for those without a cam?

We do this sort of testing at JPL. We have a large bell jar (6 ft across or so) that we put antennas and high power RF components in and then pump down to a vacuum or fill with simulated Mars atmosphere.

Mars gas is mostly CO2, Argon, and CO.. so not far off your idea of a neon room.

Hi OM,

Research the topic of choking the feedpoint to reduce noise. This may
help that (and it will certainly help with other issues), but noise
comes in many flavors. Listen at different times of day/night over
the next week. I bet you will hear a world of difference without
doing anything else.

We have a new signal generator here at the Labs, but it came without any documentation. We've been hoping to find out more about it, and your suggestion gave us a clue for a test to try. We have a limited set of loads, only from 40 to 60 ohms, but we can add some known reactance in series with that. When we put an accurate 50 ohm load on the generator, we measured exactly 1 watt with our accurate RF power meter. When we changed the load to 40 ohms, the power went up to 1.238 watts, and with a 60 ohm load, it was .839 watts. When we add reactance, either capacitive or inductive, the power goes down, so we're pretty sure the generator output doesn't look reactive. Beaker is having a little trouble with the math on this one. Could you help him out? What sort of output impedance does this generator have?

Oh, and we thought to do another experiment. While the generator was operating, we sent a short burst of RF down a 50 ohm transmission line to the generator's output. Because the power measurements seem to say the generator's output resistance is very low, we thought we would see a return pulse, delayed by the round-trip time down the 15 meters of high-quality cable. But we didn't see any echo. What could be going on? We double-checked everything, and even looked into the line next to the generator with a high impedance probe. We can see the burst going in there, but still nothing comes back.

If you have a suspicion that the generator might be 50 ohms, and you have a 50 ohm load, then the output voltage should fall by 6.02dB when the nominal load is connected (compared to o/c).

One of the simple tests that is often used to verify that a generator is loaded properly is that adding a second nominal load in parallel reduces terminal voltage by 3.52dB. This test is often easy to perform, use a power meter for the first termination, watch the reduction in indicated power when a double termination is applied. Be mindful that transmission line lengths need to be short wrt operating frequency.

Some numbers:

1st termination reduces output by 6.02dB;
2nd termination reduces output by 3.52dB;
3rd termination reduces output by 2.50dB;

Owen

With the "accurate RF power meter" determination of 1W, it appears to
be a precision source (of 1W). The output impedance IS the 50 Ohm
resistance you applied to it. This loading at the output terminals is
a conventional usage of a precision source.

Terman elaborates on Thevenin`s theorem on page 74 of his 1955 opus. From Fig. 3-19 (b) on page 75, I would suggest loading the generator with resistance until its open-circuit voltage is cut in half. That resistance should equal the internal impedance of the generator which you have already determined is resistive. Provided you don`t maintain that sort of overload too long on your 1-watt source, you should do no damage to it.

I read your other thread and the replies thus far to this one. I
never had the luxury of a tower, so I installed all mine in trees.
The last time I had one fall, I changed the way I did things a little.
I created a pilot line which was a string that went from the base of
one tree to the base of the other with plenty of room to lower the
middle to the ground. Then I ran the string thru the center
connection for the coax (It wasn't a balun, but had an eyelet on top)
and ran that string thru the eyelet. Then, the ends of the antenna
were pulled up by another piece of string. The tension was lowered
enough to allow for the sway of the trees, and the string going thru
the eyelet was just let very loose. It was loosely tacked to the trunk
of each tree such that any pressure would release it. The antenna
might fall, but I always had a pilot string to pull up a new line for
the antenna.

I always used mason's twine to raise my antennas. needless to say, I
replaced it every year. the antennas were only pulled down by a storm
once and once when I haphazardly tightened the strings too much to
allow for the sway of the trees.

My pilot line idea would have failed to work, not because of storms,
but because of branches. When I moved, the tree limbs had grown into
the wires and I barely was able to recover the antenna when we moved
out. Now I live in an apartment and have no usable trees.

I used #14 copper strand (THHN) and never had a problem with the wire
breaking or having problems with it. i have had as many as 6 wires on
the dipole, but I found that was too much to handle, keep untangled,
etc. I reverted at the end to two 4 wire antennas and later to a 135
foot dipole with twin-lead feed into a tuner. With the latter I could
tune anything.

BTW, I don't know if you use an amp or not, but if not, you can get
away with fairly small wire for the higher bands. If you feel you

need the strength of the longer one (presumably 80 meters), you can use some #18 wire to hang the other dipoles on. My dipole was a parallel fan in which all the elements were separated by pieces of PVC for spacers. To some degree, the more the merrier.

Good luck, let us know how it turns out.

The higher antenna will increase reception. You may have it near
wires or something in the house that is making noise. If you don't
have a balun, you may wish to make or use one on your line. Make sure
your rig is well grounded.

As stated above, there are lots of things that can cause the noise.
When you get the antenna raised, keep us posted and be more specific
of what the noise sounds like and maybe we can help find the source.

Welcome aboard and good luck.

So you don't like my example? Well I can use yours then.

While you use the word 'power', the real analysis in your example is
all
done with volts. This is excellent and helps demonstrate my point that
'reverse power' is not needed as an explanation. We can carry on from
the analysis you have done and compute some powers. The real power at
(c)

is 0 Watts (the voltage is 0 at all times so using P=VI, the power must
be zero). Assuming that when you say "drive 5 volts", you mean that the
voltage source in the Thevenin equivalent generator is set to 10 V,
the 'forward power' at (c) is 0.5 W and the 'reverse power' is 0.5 W.
When subtracted, these produce the expected result of 0 W which agrees
with the actual computed power. All is well. (And yes, the Bird works
for determining this result).

Now consider someone who believes in the reality of 'forward' and
'reflected power'. There is 0.5 W of 'forward power' which reaches
the generator at the right. Since the impedance of this generator is the
same as the characteristic impedance of the line (or the left generator
in this example because there is no line), there is no reflection
so the 'power' must go into the generator. Similarly with no reflection,
the 'reverse power' goes into the generator. Where does this power go?
If 'reverse power' is real, then it needs to be accounted. Since there
are many examples for which this accounting can not be done
it leads to the inescapable conclusion that 'reverse power' does not
really exist. (Please though, this does not mean that forward and
reverse voltages and currents do not exist. The fundamental error
being committed is that it is not valid to multiply the voltages and
currents computed using superposition to produce powers that actually
represent flowing energy).

Any reader is invited to prove me wrong by providing an accounting for
the 'reverse power' when it reaches the generator whose output impedance
matches the characteristic impedance of the line (i.e. no reflection).

I suggest that you have quite mixed up your impedances here
thus rendering all further analysis invalid.

At any point in the system there are 4 impedances.

There is the characteristic impedance looking left and the
characteristic impedance looking right. For systems in
sinusoidal steady-state, there is also the effective impedance
looking left and the effective impedance looking right.

The characteristic impedance is dependant only the elements of
the system. It does not depend on the length of the line or
the frequency of excitation. At changes in the characteristic
impedance, reflections occur. This impedance can be used for
transient as well as steady-state analysis of a system.

The effective impedance is dependant on the characteristic
impedances of the components of the system, as well as line
length and excitation frequency. It can only be used for
steady-state analysis. It does not cause reflections.

Until these impedances are kept straight in discussions, there
is no hope for correctness.

Below is a link leading to a documented, real-world RF pulse measurement to think about.

The reflection results from an antenna mismatch at the far end of ~1,600 feet of air-dielectric transmission line. A directional coupler and calibrated, step attenuator allow for accurate measurement of the weak return pulse amplitude in the presence of the much greater incident pulse.

Note that the reflection is (barely) seen even in the incident display, time-aligned with its location in the reflected display.

Reflections DO exist in such systems, but measuring them requires appropriate instrumentation and methodology.

Destructive interference at the generator output
terminal is all the accounting one needs.

Here's a mental aid to help see what happens to
the reflected energy. Assume the output impedance of
the generator and the characteristic impedance of the
line are Z1. Assume THE GENERATOR SEES Z2 AS A LOAD.
Z2 is a general case impedance and could have any
value depending upon the load ZLoad which is not
equal to Z1. The load is mismatched and therefore
Pref1 is not zero.

Gen---Z1 t-line----Zload<>Z1
Pfor1-->
<--Pref1

You say reflected energy flows into the generator.
I'll show you why it does NOT and that total
destructive interference is responsible for
eliminating reflections at the generator.

Add any length of lossless transmission line
with a characteristic impedance of Z2 at the output
of the generator (nothing changes) so it looks like:

Gen---Z2 t-line---+---Z1 t-line----load<>Z1
Pfor2--> Pfor1-->
<--Pref2=0 <--Pref1

Pfor1 and Pref1 are the same values as above.

The Z2 t-line has NO reflected waves because it
is terminated in its characteristic impedance Z2.
The Generator continues to see Z2 as a load. One
has to admit that nothing at the Generator output
has changed. THE GENERATOR SEES EXACTLY THE SAME
LOAD IMPEDANCE IN BOTH CASES. NOTHING HAS CHANGED
IN THE SYSTEM EXCEPT OUR ABILITY TO ANALYZE IT.

Now a simple energy analysis will indicate what
happens to the reflected waves on the Z1 t-line. Since

Pref2=0, the system is Z0-matched to Z2 at point '+'.
Total destructive interference is what happens to the
reflected waves on the Z2 t-line. All of the reflected
energy is re-reflected back toward the load at the Z2-
match point '+'.

NONE OF THE REFLECTED ENERGY REACHES THE GENERATOR SO
NONE OF THE REFLECTED ENERGY CAN BE ABSORBED BY THE
GENERATOR IMPEDANCE.

So there you have it - a detailed mathematically based
reason why the reflected energy does not make it into
the generator in your example. To fully understand why
zero reflected energy flows in the generator, one needs
to understand superposition along with destructive and
constructive interference. This is covered in more detail
in my WorldRadio Energy Analysis article at:

http://www.w5dxp.com/energy.htm

I would recommend that everyone interested in this subject
read the "Optics", by Hecht chapters on superposition and
interference of EM waves. It is the best treatment that
I have seen in writing.

No, I may have confused you but I did not mix up the
impedances. What the generator and reflected wave "sees"
above refers to the effective or virtual impedance, the
ratio of V/I designated by Z1, Z2, etc. The characteristic
impedances are designated by Z01, Z02, etc.

> At any point in the system there are 4 impedances.

Yes, nothing I said disagrees with that. I will try to
draw an ASCII block diagram from now on.

Yes, nothing I said disagrees with that.

> Until these impedances are kept straight in discussions, there
> is no hope for correctness.

OK, I will insert the impedances for you in what you quoted
above.

This is a lot like the 1/2WL W7EL example in his food for
thought articles.

50wGen---1/2WL open-circuit stub---Z=infinity
Pfor=50w-->
<--Pref=50w

The generator is *NOT* matched to the load as it sees an
open circuit (effective Z=infinity) and cannot continue
to stuff 50 watts into the open circuit. The generator
is as mismatched as it can possibly be. The reflected wave
also sees that open circuit (Z=infinity) and is 100% reflected.
The reflected wave encounters the source wave which puts the
voltages in phase and the currents 180 degrees out of phase.
That's what happens at an open circuit.

Since the generator is not delivering any power and there is
a forward power and a reflected power, the reflected power is
supplying the forward power, i.e. being 100% re-reflected. The
re-reflection is associated with total destructive interference
toward the generator and total constructive interference
toward the load. Anything else violates the conservation of
energy principle.

Your example assumes that the reflected power will see the 50 ohms of
the generator. And I had shown you a condition where it will see a short
no mater what the 'output' impedance of the generator.

It is a short. It is just that simple. If you have any kind of lab, take
a long piece of coax and drive it with a pulse and watch with a scope.
Find out for yourself that energy will reflect off a short.

No. (c) is a short. It is just that simple. The power does not flow past it 'into the other generator'. If you have any doubt that power is reflected from a short you have not made the observation. And if you have not made an observation that contradicts this, you can not make the claim of a contradiction.

<snip assumptions based on a false premise>

> Any reader is invited to prove me wrong by providing an accounting for

If you stick to the premise that the reflected power sees the generator impedance it can't be 'proven wrong'. I can say that gravity doesn't exist all day long but that won't make it so. The observation will 'prove' me wrong.

Thank you, Mr. Clark. But I'm having trouble reconciling what you wrote with what Mr. Harrison posted about the output impedance being equal to the conjugate of the load which dissipates the most power. Clearly the 40 ohm load dissipates more power than the 50 ohm load, so we don't see how your answer and Mr. Harrison's posting can both be correct.

I have followed this thread with interest There are some who seem to
dispute the existance of reflected power and its ability to do damage.
My answear is that reflected power can certainly do so any one want to
run a completly detuned antenna to prove me wrong may do so at their
expence and risk. as to it causing heat in the amp of course not the
extra work that the amp has to do to "push" the signal to the antenna
does. if a semiconductive device is over worked then it will produce
heat.
The old thermonic valves are far more tolerant than semiconductors.

It appears that the internal resistance of the
Thevenin equivalent circuit was chosen to be
~1 ohm. Maximum power transfer of ~13 watts
should occur when the load is ~1 ohm and the
current is ~3.6 amps with ~3.6 volts across
the 1 ohm load and across the ~1 ohm generator
impedance. How one gets 13 watts out of a source
rated for one watt is a non-linear physical
design problem, not a linear theory problem.

Truly, we have found the root of the disconnect.

Kindly compute the reflection coefficient at the connection where
a 50 Ohm line is driving a 75 Ohm line.

For your convenience, recall that RC = (Z2-Z1)/(Z2+Z1).

Now redo the same, except that the 75 Ohm line is one-half wavelength
long terminated in a short.

If you get the same answer, then you will see why the reflected
voltage in the example does not encounter a discontinuity at the
entrance to the generator and is therefore not re-reflected.

If you get a different answer, then some study of reflection
coefficient
is in order.

Reflected power doing damage is an overly simplistic
way of viewing things. The reflected wave is capable
of causing damage without giving up any of its energy.
It is not the energy in the reflected wave, per se,
that causes the damage. It is the interference pattern
established by superposition of the forward wave and
the reflected wave that causes the damage.

If the reflected voltage arrives back at the source
in phase with the forward voltage, that constructive
voltage interference can cause an over-voltage condition
that blows the finals. This over-voltage condition actually
reduces the dissipation in the finals because it is
accompanied by a destructive interference, reduced-current
condition. The finals are actually cooler than normal
when the over-voltage begins to fry them.

Of course, a Thevenin equivalent source doesn't suffer
from an over-voltage problem. Power consumption within
a Thevenin equivalent source actually decreases during
constructive interference between the forward and
reflected voltages.

If the reflected current arrives back at the source
in phase with the forward current, the result can
be an over-current condition which can indeed cause
over-heating and failure.

What happens in the finals depends upon the phase
of the reflected wave. Solid-state finals are
usually protected from both over-voltage and
over-current by detecting the SWR. A fold-back SWR
limit of 3:1 limits both the ratios of Vmax/Vmin
and Imax/Imin to 3:1.

Truly, we have but it is not what you think. A
source doesn't obey the passive reflection rules.
The V/I ratio encountered within a source is
active, not passive. Active V/I ratios can and
do cause reflections.

Cecil,

Ya know, it is possible to simply add and subtract voltages. It is not required to determine an "interference pattern". Solid state electronics are damaged by high voltage or high power dissipation (or both). No "interference patterns" required.

Perhaps the manufacturers could add exactly the correct length of transmission line inside the transceivers so that the wrong kind of interference could never occur at the finals.

Cecil,

You have highlighted a really useful mathematical aid.

Namely, include the desired answer as a basic condition for setting up the problem, and the proof becomes easy.

It is absolutely necessary to understand the interference
patterns if one wants to track the energy through the
system.

><<SNIP>>
>> What are the pros and cons of fan dipoles like this?....

We used one of these at a local mall for "Kids' Day" last January.
Formula-cut for 20/15/10 and errected about 25 feet high (best we
could do at the mall), with NO special "fanning" at the center, but
the ends were about 2 feet apart, and the VSWR was about 6:1 on all
bands (fortunately, we had taken a tuner).

If your VSWR is low, maybe we should have done a bunch of pruning
and cutting, but we didn't think far enough ahead!

Richard, it's been my observation that many of those who argue are clueless concerning the phase relationships
required to obtain the destructive and constructive interference that achieves the re-reflection of the
reflected waves. A reflection resulting from a discontinuity in the path of a signal delivered by a souce is
guaranteed to be coherent with the source wave. If there is no coherence between the reflected wave and the
source wave there may be an interference, but none of the type that results in total destructive and
constructive interference relevant to impedance matching. I don't understand what you mean by 'taking only one
of two degrees of the 360.'

>
>And we return to the sine non quo for the discussion: phase.

That's true, but although RF apparently realizes that the phase relationship is relevant, he doesn't seem to
understand the details of the phase requirements that achieve the necessary interferences that accomplish the
impedance matching.

>>>If the ham transmitter designs that your paper applies to produce a total

If a tree were to fall onto the antenna the new mismatch would surely detune the transmitter, causing unwanted
dissipation, of course, but only a lid would fail to retune the transmitter before removing the tree.

IMHO, Richard, the mfgrs of solid-state rigs with no means of matching the output to a load other than 50
ohms short changed the ham, thus requiring him to be satisfied with the power fold back, or buy an antenna
tuner.

Ghosting is explained by reflected voltages and currents.

I notice that you frequently use this example, unfortunately
never completing the analysis.
Since you leave it unspecified, let me choose the

output impedance of the TVSG to be 450 Ohms. Now there is
'reverse power' in the ladder line but no ghosts. Where did
the 'reverse power' go such that it does not produce ghosts?

If it is re-reflected, then it is a delayed copy of the original,
i.e. a ghost. So where does it go? Seems to me there is only
two ways and the way that does not produce a ghost is into the
generator, so we need an accounting of this power within the
generator, iff it is real power.

Of course there is no issue once you let go of the notion of
'reverse power'. The reverse voltage and current pass into
the generator since the generator is matched to the line and
nothing is reflected.

And since multiplying reverse voltage by reverse current does
not, in general, produce a real power, there is no power to
account for.

But, again, to argue that 'reverse power' is real, it becomes
necessary to explain where it went.

Love to, once it is no longer used as an explanation for these
phenomena. Simply changing the name to something else won't help.

Hi Walt,

I offered:
>> they take only one or two degrees of the 360.

Arguments that are confined only at 0 or 180 (the one OR two degrees)
and are submitted as proofs as though they boxed the compass. All too
often I've seen one condition (at one phase angle) offered as a
negation of internal heating to prove the source lacks its own
internal resistance. When I've taken exactly the same circuit and
explored the 180th degree alternative, I've demonstrated melt-down
clear and simple. The dissipation of energies does not always lead to
this consequence, but if we were to average the analysis over a
complete 360 degrees, we can only arrive at the obvious evidence of
resistance and calories expended.

Then asking a question to clarify would be in order. To me, it reads
quite ordinarily as a statement of symmetry. In my own words, it
would say that if a tank circuit can pass energy from source to load
in one direction, it can certainly perform the same transformation in
the opposite direction. After all, that is the function of
transformation and a passive circuit composed of L and C is strictly
linear. Circuit analysis allows us to treat a load as a source in the
complete circuit description.

The initial mismatch and its correction do not describe the same
condition. There is a first state, and then the operator imposes a
second state in reaction.

Of course, but then this is a single instance: a mismatch causing possible increased dissipation within the source. "Possible" is in proportion to phase relationships; dissipation is always.

If you retune to correct the mismatch's potential to destruction (or to provide full power through-put); then you have moved to another state or configuration. That new state admits the potential negative consequence of the first state.

A tube rig requires the same means of matching. It's a wash.

Keith Dysart wrote:
> Ghosting is explained by reflected voltages and currents.

Z0 has a large resistive component and a small reactive component. Vref*Iref = Vref^2/Z0 = Iref^2*Z0 = real watts You cannot have reflected voltages and currents that contain zero energy. In fact, a reflected TEM wave must have its E-field and H-field 90 degrees apart. The watts contained in the reflected EM wave are ExB, i.e. real watts.

In a flat-matched system the forward traveling wave is the only one that exists. Would you also argue that the forward traveling wave doesn't contain any energy? All traveling waves contain energy including reflected traveling waves.

Into heating the 450 ohm circulator load resistor that you would have to install to get the generator impedance to exhibit 450 ohms to the reflected waves. Otherwise, the generator will exhibit a mismatch to the 450 ohm line. It is *impossible* for the generator to see 450 ohms when looking into a Z0=450 ohm line with reflections. So it is impossible for the reflected wave to encounter a V/I ratio of 450 ohms in the active generator (unless a 450 ohm circulator resistor is installed).

> And since multiplying reverse voltage by reverse current does
> not, in general, produce a real power, there is no power to
> account for.

Suggest you review transmission line theory. If reverse voltage and reverse current exists, the transmission line forces their ratio to be Z0, i.e. 450 ohms, i.e. in phase. V*I*cos(0) = watts. Since reflections are causing ghosting, it is prima facie evidence that "real power" is being extracted from the reflected wave.

It is a problem of apples and oranges. Your source is not
representative of either a commercial transmitter, nor a amateur
transmitter. It is a precision source. It has no need to exhibit
impedance matching, and is thus not designed to perform that purpose.
It is happy to run quite inefficiently as efficiency is a discardable
quality. Rather, it is incumbent upon you to enforce matching by
careful load selection. Otherwise, its utility is wasted and makes it
a rather expensive choice for a general purpose signal generator.

> 450 ohm circulator resistor is installed).

You are trying too hard. Even your problem statement said
"no circulator". So I offer a simple example of such a
generator: a voltage source connected by a 450 Ohm resistor
to the output terminal. Voila: a generator with 450 Ohm
output impedance. Not too efficient perhaps, but the design
is used when quality source matching is desired or when
reflections need to be suppressed but it is impractical to
terminate the load in the characteristic impedance of the
line.

Now back to the problem... and the questions...

> Actually, "reflected energy" rather than "reverse power".

I notice that you frequently use this example, unfortunately
never completing the analysis.
Since you leave it unspecified, let me choose the
output impedance of the TVSG to be 450 Ohms. Now there is
'reverse power' in the ladder line but no ghosts. Where did
the 'reverse power' go such that it does not produce ghosts?

If it is re-reflected, then it is a delayed copy of the original,
i.e. a ghost. So where does it go? Seems to me there is only
two ways and the way that does not produce a ghost is into the
generator, so we need an accounting of this power within the
generator, iff it is real power.

Of course there is no issue once you let go of the notion of
'reverse power'. The reverse voltage and current pass into
the generator since the generator is matched to the line and
nothing is reflected.

Oh I can do the math, and the units are definitely Watts
but that doesn't necessarily mean they offer any reality.
The toaster in my kitchen has 120 Volts on it and the lamp
is drawing 1 Amp (and the two are in phase), but that does not
mean that 120 toaster-lamp Watts has any meaning.

The generator is an *active dynamic source*. It does
not have a 450 ohm output impedance just because you
install a 450 ohm resistor. Just as soon as reflected
waves are allowed to reach the source, the source
impedance dynamically shifts away from the 450 ohm
value.

I notice that you've skipped the important question posed in
the example. I'll try again.

Use my generator: voltage source, 450 Ohm resistor to the output.
No circulator.
Drive your system: 450 Ohm line terminated with a 75 Ohm TV receiver.

TVSG-----1000 feet 450 ohm ladder-line---75 ohm TV RCVR

Ghosts or no?
If no? Where did the 'reverse power' go?

If ghosts? Well, think very carefully before choosing this option
because there aren't.

There will be ghosting but because of the attenuation
in the 450 ohm series resistor, the ghosting will be
below the level detectable on a TV screen by the human
eye.

3005. Litz wire for AM Antenna Rod?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-24 04:29:04 UTC
From: Bill Bowden <wrongaddress@att.net>
Message-ID: <1174710544.066675.261910@n59g2000hsh.googlegroups.com>
Source record: 44271

How much improvement can I expect using Litz wire to wind a AM ferrite
Rod antenna as opposed to using solid copper wire?

Is it worth the trouble to obtain Litz wire, or can I expect almost
the same response at say 1 MHz using regular enamaled copper wire?

-Bill

3006. Nutty Antenna Idea -- Complete with Rhetorical Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-24 06:45:54 UTC
From: "Sal M. Onella" <salmonella@food.poisoning.org>
Message-ID: <CO3Nh.78006$p17.47735@newsfe11.phx>
Source record: 44272

I have two multiband trap verticals They are not exactly the same, but close. Obviously they're intended to be mounted vertically above a ground.

What happens if I mount them horizontally, base-to base? If I feed one with coax as designed, would it see the other one as a counterpoise? Could I remove any base matching components and feed them both with a 1:1 balun, in effect duplicating the function of a horizontal wire trap dipole?

I'm really impressed with the lower noise of a horizontal antenna. Screw the directionality drawbacks of a horizontal! I can hear more stations.

I am having great fun with HF. My 10 meter copper pipe dipole is laying on the roof with one element extended using a short clip lead and some RG-6 TV coax. Tonight, my Kenwood TS-120 reached out from San Diego for a QSO with New Zealand on 20 meters, my first contact outside this hemisphere. Neat.

3007. antenna suggestions ?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-24 07:56:54 UTC
From: Nick <a@b.com>
Message-ID: <aR4Nh.20785$0Z1.8430@newsfe7-win.ntli.net>
Source record: 44273

I have a friend who is visiting southern Spain shortly, has a 5 Watt all band portable set
and at the moment, just a "Miracle whip" for an antenna...

We are trying to make the contact between there and the southern UK and so trying to give ourselves
the best chance of making it. The UK station is 100 watts and W3DZZ trapped dipole, or a low horizontal
loop at about 15 feet approx 240 feet long, or a 40 foot vertical with several buried ground wires and earth rods
at base, the last two being matched with an SGC 230.

He is a very dry/arid area, although on reclaimed salt marshes, so guess ground conductivity might still be good
in a dry stone / brick built house with a roof balcony
approx 10 metres above ground. He can only lash up a temporary solution for the time he operates, so
perhaps a long wire/counterpoise, a dipole of some sort or an inverted V, pre-made at home before he goes

Can anyone recommend what aerial will likely give us best chance of making the contact, on which band
and at what time of day ? The distance is approx 1150 miles between us.

Thanks,

Nick

What you would have is a trap dipole, a fairly common antenna. With out
seeing the antennas I am not sure how the twoo different types would
intereact but its worth a try. You will probably need a tuner.

It would be much more convincing if you were to compute the
magnitude of the ghost rather than handwaving an answer.

Though when you do so, you will find that it is exactly zero,
so be prepared.

I think you will find some degradation in the Q and more interwinding
capacitance.
The extra interwinding capacitance might make it more difficult to tune the
upper
end of the AM band. (If you are trying to tune 540khz to 1710khz.)
Run some tests on a loop from an existing AM loop coil with litz wire, then
rewind it
with solid wire. Let us know the results.

its all ghosts and mirrors!

forget power, forget energy, they are products of other calculations. all
that is needed is impedance and voltage OR current. once you know voltage
OR current and the impedance you can calculate all the rest.

What would you do if you were dealing with EM light waves
instead of EM RF waves? Optical physicists don't have the
luxury of dealing with "impedance and voltage OR current".
They are forced to deal with the essence of EM waves which
is photonic energy. They have done it for over a century
and have learned a lot about the nature of EM waves. They
did not "forget power, forget energy".

As I said, it was a rough computation based on your 450
ohm series padding resistor and a lot of simplified
assumptions about the configuration of the system.

In order to avoid ambiguity, would you please give us
better specifications for the source? Ramo and Whinnery
warn us not to draw any conclusions about what happens
inside a Thevenin equivalent source so your specification
must be an achievable well-defined real-world source.
How about a class-A linear amplifier with no filters,
no impedance transformation, and no protection circuitry?
Vrms/Irms = 75 ohms Vrms*Irms*cos(0) = 1 watt

The amount of interference cannot be calculated without
magnitude and phase. Shall we assume that the 450 ohm
line is an integer number of wavelengths and lossless?
i.e. Z0-matched to 75 ohms?

If you require detailed calculations, more specified
information is needed.

I second Frank's recommendation of Bowick. It also has very good
information on matching networks and transistor biasing.

Standard analysis can tell us quite a bit about the situation
without the need for further information. The information
we have:
- Generator with 450 Ohm output impedance
- connected directly to a 1000 foot line with 450 Ohm
characteristic impedance
- connected to a load with 75 Ohm input impedance.

Remembering that reflection coefficient is RC = (Z2-Z1)/(Z2+Z1) let
use compute the RCs at all the connection points:
RCgen-line = (450-450)/(450+450) -> 0
RCline-load = (75-450)/(75+450) -> -0.714
RCline-gen = (450-450)/(450+450) -> 0

Let the output of the generator into a 450 Ohm load be Vout.

Forward voltage supplied by the generator into the line:
Vfwd = Vout
This is also the Vfwd that reaches the load (for the purposes of
example we are dealing with lossless lines).

The reflected voltage at the load:
Vref = Vfwd * RCline-load = Vfwd * -0.714 = Vout * -0.714

The voltage applied to the load:
Vload = Vfwd + Vref = Vout * 0.286

The voltage reflected from the load that arrives back at the
generator:
Vref = Vout * -0.714

The amount of Vref reaching the generator that is reflected back
to the load:
Vrefref = RCline-gen * Vref = 0 * Vref = 0

There for no ghosts since there is no re-reflection.

A few other things of possible interest...
Power delivered to the load:
Pload = Vload * Vload / 75 = Vout * Vout * 0.0816 / 75
= Vout * Vout * .0011
This is the actual power that flows in the line.

Forwarwd power as indicated by a directional wattmeter in the line:
Pfwd = Vfwd * Vfwd / 450
Reverse power as indicated by a directional wattmeter in the line:
Prev = Vref * Vref / 450

Net power flowing in the line:
Pfwd - Prev = (Vfwd*Vfwd)/450 - (Vref*Vref)/450
= Vout*Vout/450 - Vout*RC*Vout*RC/450
= Vout*Vout*(1-(RC*RC))/450
= Vout * Vout * 0.0011
Which is the same as the load power; this being as expected
since directional wattmeters are useful for obtaining the
net power.

It is also useful to know what we can not compute from the
provided information....

The voltage at the generator output and its phase with respect
to the current since this is dependant on the velocity factor
of the line and the signal frequency. Though if the output is DC
(e.g. a step function) than this can be easily computing for
the situation after one round trip delay.

Generator dissipation since we would need to know the internal
construction of the generator and the actual voltage and current
phase at the output of the generator.

Still, using conventional techniques we have derived quite a
bit about the system without knowing the internals of the generator.

Cecil, are you saying that your techniques can not produce any
derivations without knowing the internal construction of the
generator and the length of the line (in wavelengths)?

Yeah I thought about that too after my inital post. It would be a bear to
make a rotateable dipole using this if its anything like my old trap
vertical.

yes they do. but photons are propagating em waves, they aren't currents and
voltages, they are E and B fields. you can do the exact same calculations
using either E or B and the refractive index or epsilon/mu. again, all you
need is 2 of them, and you can compute the third, and then you know it all.

There are a number of techniques to ensure that the
reflected waves encounter an impedance of 450 ohms
but none of those techniques are implemented in
amateur radio transmitters. Your generator is
obviously equipped with a circulator load of 450
ohms, 450 ohm attenuation pads, or some active
feedback. Given that, your analysis is correct but
moot. Your point is already known and accepted by
every initiated person including me.

I freely admit that if the proper circulator load
exists or if 450 ohm attenuator pads exist, they
will dissipate the reflected power by heating
up the circulator load resistor or the pads.

But it's tough to argue that there is no energy in
the reflected waves while they are being used to boil
water.

True, but how do they measure two of them? Ever
tried to measure the E-field of visible photons?
Hint: It is an irradiance (power density) time-
averaged measurement proportion to E^2.

While it might be, none of the above are necessary nor
included in the example I have analyzed.
A simple voltage source in series with 450 Ohms resistor
or a current source in parallel with one will produce
exactly the same results.

Look carefully at the analysis and you will find no
evidence of any of the items you have mentioned above,
unless you consider the 450 Ohm resistor to be an
attenuation pad. (Though it is this resistor which matches
the line and ensures there is no reflection).

> Given that, your analysis is correct but
> moot. Your point is already known and accepted by
> every initiated person including me.

Not you, I suspect, since you seem to find it necessary
to add some components which were not in the description
of the setup.

> I freely admit that if the proper circulator load
> exists or if 450 ohm attenuator pads exist, they
> will dissipate the reflected power by heating
> up the circulator load resistor or the pads.

Yes, indeed they would. The more challenging case for
you is the example I presented without these components.
How do you explain the absence of ghosts? And the
unaccountability of the 'reflected power'.

While an example with a circulator makes it easy to
locate and account for the 'reflected power', there is
more to be learned by studying the example without.

If you can not demonstrate a flaw in the analysis then you
may wish to explore why the example without a circulator
(or other additional components) causes you difficulty.

> But it's tough to argue that there is no energy in
> the reflected waves while they are being used to boil
> water.

While you can construct examples where the 'reflected
power' will boil water, there are alternate examples where
the total system dissipation drops in the presence of
'reflected power'. So sometimes 'reflected power' boils
water and sometimes it does not. Not a very reliable source
of energy it seems.

But I do suggest going back to the example. If there is no
flaw in the analysis, please explain where the 'reflected
power' goes.

Considering only the attenuator case, you suggest in such a general statement that reflected power always increases the dissipation in a real source that includes an attenuator for the purpose of constraining the equivalent source impedance.

Such a suggestion is incorrect in the steady state, some loads may increase the generator's internal dissipation, some may decrease it depending on the attenuator circuit.

I've done it with pairs of identical "hamsticks" (not multiband, but
quick-disconnects made it relatively easy to change bands), coax fed,
and mounted (horizontally, pointed fore and aft, of course!-) about
two feet above the cab of my pickup. It made a GREAT NVIS HF antenna!

So let me get this straight, Yuri,

A cold snap in your neighborhood means that Global warming is
invalid?

I always offer this challenge:

A number of gaseous components naturally occurring in the
atmosphere have an effect that tends to retain heat. These are
collectively referred to as greenhouse gases. That paragraph is a fact.
It has been experimentally proven.

Through various methods, the amount of at least one of those gases
has increased significantly since the beginning of the industrial age.
That is a measurable fact.

note: there have been some fairly dramatic increases in other gases
that are much more "actice" in heat retention, like methane. Let's ignore
them for the purposes of this argument.

Give me a compelling and scientific reason why proven scientific
facts are not having a measurable effect on the earth's temperature. Then
invalidate the apparent measured effects that would tend to support the
warming. I am willing to abandon the thought of global warming if someone
can give me a real and non-political argument.

Of course, that means no offhand remarks about Left wingers,
commies, or the usual suspect trotted out as some kind of "proof" that
satisfies only those who get their science news from AM radio talkshow
hosts.

From a right-winger who looks beyond the politics.

(p.s. no one has done it yet)

> trend that started 20,000 years ago? Caveman
> campfires?

Hardly likely Cecil. The amount of CO2 in the atmosphere has varied quite a bit over time. Lot's of sources of it, and lots of sources of other greenhouse gases.

Certainly the Deccan Traps indicate that volcanic activity likely had some effect on CO2 atmospheric content. That was quite a bit before 140,00 years ago.

The sun itself undergoes some variability. It is likely that many things contribute to temperature variations.

Human effects would hardly have made any impact before our population growth and inadvertant release of greenhouse gases did start to have that impact.

Let me ask a question of the doubters. Say that a new ice age came about. Say that Canada and much of the north were starting to freeze over. In the sothern Hemisphere, the same was happening. All this was meaning that Humanity was going to loook at a huge die off, as useable land were to shrink, and the present population became unsupportable.

But perhaps a way out was available. Burning as much carbon based fuels as possible would possibly raise global temperatures some. Perhaps land at the fringes would become able to support agriculture again, instead of being glaciated. Perhaps more humans could be saved.

Would that be okay then? Would it be worth the effort? Or should we just die off because it was a liberal plot? ;^)

I hadn't bargained on rotating it, although that's not out of the question. I think those verticals are about 20 pounds each, so it would be a project. I will weigh them tomorrow. I do have a rotator thrust bearing that I once used with a monster VHF TV antenna.

The Hustler four band (10, 15, 20 , 40) is 35 feet tall. The other antenna is a five-band, but I don't have the specs here at hand. It's presumably the same, unless they got 80 with some folding tricks, in which case I don't know how tall it would be.

Depending on where I would put a rotating 70-foot horizontal antenna, I'm sure I could either prune my neighbor's tree or make contact with the power company, via their overhead lines. Did I mention I am on a city street with a 100 x 100 lot? Hm-m-m -- better not rotate.

Thanks. I don't own any of them, yet, but it sounds like a possibility.
I'm probably going to want DX, though, so NVIS isn't something that I'm
seeking. If I'm horizontal, I'll want some elevation.

Make sure your antenna is OK before you try this a lot of those old Hustlers
are good for scrap.

3041. Balun

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-25 07:16:52 UTC
From: "Mike M." <notme@invalid.email.net>
Message-ID: <1g4c03thgmh4ug188j2lobrduereqculbi@4ax.com>
Source record: 44307

I built a 4:1 balun based on an old QST article.
http://www2.arrl.org/members-only/tis/info/pdf/9008028.pdf

I used 10 Fair-Rite 2643540002 beads on each of the 2 pieces of RG-71B/U 93 ohm coax. These are #43 ferrite .562 OD .250 ID and 1.125 inches long.

Is this enough #43 ferrite to be an effective balun on 80 thru 10 meters?

The balanced side is connected to about 30 ft of 450 Ohm window line that feeds a 135 ft off center fed dipole at 75 ft from one end. The unbalanced side is connect to the coax output of an AEA ET-1 manual tuner through 20 ft of Mini 8 coax.

Will this type balun work with the high swr that it will see on some bands?

I can get a good match on 80 thru 10 meters except for 12 meters. It seems to work, but I may be converting more RF to heat than radiating. The external balun is a matter of convenience as it is a lot easier to bring the coax into the tuner than it is to bring in the window line. Would it be better to just use a 1:1 balun between the coax and the window line?

Have a look here.
http://en.wikipedia.org/wiki/Moot_hall
I remember 'Moot Hall' from my days at primary school (some 60 years
ago), learning about the Anglo-Saxons. I guess the word may possibly be
associated with 'meet', ie a meeting hall where things were debated.
However, my Anglo-Saxon is a bit rusty (not much call for it these
days).
Ian.

Hi Mike,

Perhaps, but without more data, it could be working just as well as it
appears to be.

>Would it be better to just use a 1:1 balun between the coax and the
>window line?

That is simple enough to check by simply moving one leg of the dipole
to the choked coax feeding the other side (and abandon the redundant
choked line). This, of course, returns us to my observation above.
Without more data, there is no way to say what would be "better."

Cecil was using "moot" in its legal sense: that a point had become
irrelevant, or no longer needed to be decided because of a change in
circumstances.

Or at least, Cecil tried to claim that a point made by Keith had become
moot. But Keith disputed that... and so it rumbles on.

Skin effect means that the RF current is only being carried in a very,
very thin layer, so one can silver plate the inside of the aluminum
shield and the outside of the center conductor. At 100 MHz skin depth
for copper or silver is a bit more than 6 microns (0.25 mil), so it
doesn't take a very thick layer.

I had some 1/2" diameter stuff once that laid on the ground prior to
entering the house. A year or so later and the sheathing turned to
dust.
You may see some used for cable t.v. about 1 " diameter, these use air
as a dialectric and moisture can get in. All aluminum forms dislike
bending and easily kinks and do not straighten out easily. Personaly I
would avoid
aluminum for transmission lines.

Andy writes
The difference will not be noticeable...
A higher "Q" , which is theoretically available with litz wire, is
only useful
in separation of strong signals in your applications. If you are
building
a simple receiver, your biggest problem will be stations which are
located
nearby overpowering stations which are not. A little bit of
selectivity
resulting from a slightly higher "Q" ain't gonna make squat for
difference...
..... but that's just a technical term..... Forget it and build the
damn thing...

Richard, assume a mismatched load has produced both voltage and current refleftions on the
line that result in

a particular reactive impedance at the line input. The line input is connected to the output of the
transceiver that has a pi-network output coupling circuit. When the network has been adjusted to deliver all
the available power into the line the output source impedance is the complex conjugate of the line input
impedance. In this condition the reflected voltage and current waves are totally re-reflected back into the
line, while adding in phase to the voltage and current waves from the source, respectively. Consequently, the
reflected waves do not pass rearward through the network to be incident on the plate. Only if the network is
mistuned, such as being connected to the reactive input of the line without being retuned to resonance, in
which case the excessive plate current due to being mistuned will result in an inordinate amount of heating of
the plate.

>>
>>True, but RF just hasn't said it all, because, as I said above, I don't believe he understands the details of
>>the phase requirements to achieve the match.
>
>That has not been my impression of the complete post.

Richard, try this on for size and then determine whether you believe RF understands the function of the
phasing in impedance matching:

Assume a 150-ohm pure resistance terminates a 50-ohm line, producing a voltage reflection coefficient rhoV
=0.5 at 0ï¿½, a current reflection coefficient rhoi, yielding a 3:1 mismatch. We want to place a series stub at
the appropriate position on the line to yield a match at that point. The appropriate position on the line is
where the real portion of the line impedance is 50 ohms, with a residual reactance, which in this case is
-j57.7 ohms, determined by the 3:1 mismatch. A series stub having a terminal impedance of +j57.7 ohms cancels
the residual reactance, achieving a match at the stub point.

Now to the phase relationships that occur here that I believe RF has not considered.

First, the line rhoV at the stub is 0.5 at -60ï¿½, and the stub rhoV is 0.5 at +60ï¿½, with the resultant rho =
0ï¿½.
Second, the line rhoi at the stub is 0.5 at +120ï¿½, and the stub rhoi is 0.5 at -120ï¿½, with the resultant rho =
180ï¿½.
Third, with resultant voltage and current at 0ï¿½ and 180ï¿½, respectively, we have achieved a virtual open
circuit to waves reflected from the 150-ohm mismatch, causing total re-reflection of the reflected waves at
the stub point. Proof that total re-reflection has occurred is by observing that there is no evidence of any
reflected waves rearward from the stub point to the source.

Now, when adjusting the output network of a tube-type transceiver to deliver all the available power into a
line having reflections, the adjustment of the network accomplishes the same function as the stub on the line
in the above discussion. Consequently, this is the reason why the reflected power is totally re-reflected at
the output terminals of the network, and is never seen at the plate of the amp to cause heating.

This is the concept I believe Richard Fry is not appreciating. If I'm wrong on this I hope he'll straighten me
out.

Walt

You are not allowed to deny the existence of the 450 ohm
real world load while asserting that it still exists.
If it exists, it dissipates the reflected energy. If it
doesn't exist, it reflects the reflected energy. Please
choose one or the other - obviously, you cannot have both
at the same time.

> While you can construct examples where the 'reflected
> power' will boil water, there are alternate examples where
> the total system dissipation drops in the presence of

> water and sometimes it does not. Not a very reliable source
> of energy it seems.

If reflected energy is not dissipated, it undergoes destructive
interference and is redirected back toward the load as constructive
interference instead of being incident upon the source. Why
are you having difficulty with that concept from page 388
of "Optics", by Hecht, 4th edition?

> But I do suggest going back to the example. If there is no
> flaw in the analysis, please explain where the 'reflected
> power' goes.

Again, reflected power doesn't flow so it doesn't go anywhere.
Until you understand that simple fact of physics, further
discussion is unlikely to yield valid results. "Reflected power
that goes" is only one of your many conceptual flaws. So your
first logical step would be proving that reflected power actually
flows. After you do that, we can continue to your other conceptual
flaws.

Owen, why do you feel compelled to lie about what I said?

If the reflected energy is dissipated within the source, it
increases the dissipation. If the reflected energy is not
dissipated within the source, it does not increase the
dissipation. Why is that so hard for you to understand?

That is correct Cecil but they are using a insulator instead of air
because of moisture getting in. The coax is also covered with plasic
which with the
inside insulation makes it less liable to kink or attack by ground
alkali or moisture.
Actually some of the older air insulated coax did not have a plastic
covering but these were changed out when HDTV entered the mix.
The air filled coax makes useful parts for antennas, you apply a
voltage
to the inner wire and the heat allows the spacers to soften and
separate from the outer aluminum. The outer aluminum tubing is thicker
than the norm so it can be put into use in several ways. Couplings are
hard to get unless
you manage to get some when the coax is changed out, the center wire
is solid so it is not as easy to join as corregated copper types which
are tubular in form allowing for a conductive rod to be pushed into
the joining ends and then sliding a copper tube over the outer
corregation before soldering

Bill, to give you a better background so the answer is more understandable is to think about what Litz wire does for you. When are delving into lower frequencies than AM then the skin depth required of the wire is much deeper that at higher frequencies and if the wire diameter is relatively small then the resistance goes up because even if there was enough skin depth the circumference is small. If the wire was made of many strands insulated from each other then the resistance goes down since the wires are in parallel.
As I stated earlier Litz wire is used below AM frequencies. So now let us examine what wire resistance does at A.M. frequencies say on your auto, do you think that you could tell the difference on the radio if you replace the stainless whip with say a copper wire? No I don't think so. So for starters the Litz wire is not relavent for your frequency of use and 2 the conductivity of the whip will not affect your radios performance unless you took liberties with the conductivity and replaced your whip with a wooden stick

3060. Best tiny directional antenna to get 500m range with at most 100mW at 150MHz?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-26 02:35:51 UTC
From: David Hooker <david.d.hooker@gmail.com>
Message-ID: <bkGNh.2582$tp3.24601@nasal.pacific.net.au>
Source record: 44178

Hello all,

I'm trying to make a carfinder, where a pocket-sized, keyring-attached transmitter sends a signal to a car, the car sends a reply, and the carfinder shows some kind of signal strength indication. Do this as the operator turns in a circle, and he should have an idea of where he left his car in the carpark.

In Australia, it is legal to use 150MHz for any purpose, so long as the output is limited to 100mW. I've found a pre-made transmitter unit for that frequency and power (which gets 10km with a good antenna), but I'm a novice to radio in general and am looking for pointers to information on choosing the right kind of antenna to that is small enough to fit.

In the car, I don't have much more space (I could use the car's antenna instead), but it would need to be omnidirectional.

Thankyou for your time.

Jim, your point is excellent. Amateurs would be hard put to design an efficient radiator array using known electrical laws as stated by Maxwell. Imagine trying to design a yagi antenna using only Maxwells observations
instead of the 'suck it and see' empirical methods used today. Known electrical laws are simplicity in themselves usually just a paragragh in length, could you supply the same for the Yagi? As I have stated earlier the Yagi put antenna design back by over half a century since it diverted thinking though around known electrical laws to taking the easy empirical way out.

Cecil,

Paragraphs 1 and 2 appear to declare exactly the opposite behavior for energy (power).

Is there some subtle re-definition going on to allow "redirected back toward the load" and "it doesn't go anywhere" in the same message?

What is it that you are trying to say?

Actually, the loss characteristics of solid jacket heliax depends much more on the dielectric material, physical diameter, and the size of the center conductor, than it does on the jacket material. Also, aluminum is a pretty good conductor anyway.

From March 14:
"2. The amplifier is now powered down and the load resistance RL is
measured across the input terminals of the resonant pi-network tank
circuit (from plate to ground) with an HP-4815 Vector Impedance
Meter."

>Richard, try this on for size and then determine whether you believe RF understands the function of the
>phasing in impedance matching:

...

>Now, when adjusting the output network of a tube-type transceiver to deliver all the available power into a
>line having reflections, the adjustment of the network accomplishes the same function as the stub on the line
>in the above discussion. Consequently, this is the reason why the reflected power is totally re-reflected at
>the output terminals of the network, and is never seen at the plate of the amp to cause heating.

If you follow my separation of arguments above, you will find it
demands that the source MUST have the intervention of an outside agent
to resolve its probability of facing destructive energy. In the arts,
this is called Deus ex Machina. In the world of science, we would
have to say that the source is extremely non-linear when its internal
state of Z (a distinctly non-Thevenin characteristic) changes to
follow the load.

In short, of course no energy finds its way in, we twisted knobs to
make that a self-fulfilling prophecy. Without this intervention
reflected energies present the real probability of destruction by
heat.

Paragraph 1 is about energy and doesn't mention power at all.
Paragraph 2 is about power and doesn't mention energy at all.

Energy is as different from power as length is different from
velocity. Do you also get length and velocity confused?

> Is there some subtle re-definition going on to allow "redirected back
> toward the load" and "it doesn't go anywhere" in the same message?

Here's a quote from my web page:

"The term "power flow" has been avoided in favor of "energy flow".
Power is a measure of that energy flow per unit time through a plane."

The dimensions of power flow would be watts/sec. I'm not sure
what quantity watts/sec would represent or where it would go.

Ahhh. OK, if I can legally call this a "radiodetermination transmitter" then I can use up to 25W (!) at 7.6-7.7GHz; otherwise the highest frequency I can use is 2.4-2.425GHz at 100mW.

But if I'm in a carpark and I'm using such a high frequency (please excuse me, I'm a novice) but wouldn't I have trouble with reflections from the metal of the cars and concrete around me?

Well, according to this website, Litz wire will increase the Q factor
of a ferrite rod antenna by 6 times or more at 943Khz. The attainable
Q value is 141 with solid copper wire and 1030 using Litz wire. Quite
a significant difference. Of course the bandwidth is is only about 500
Hz with a high Q value and much wider at the lower Q, which may be
desirable. But it's much easier to start with a high Q and work down,
than the other way around.
Very easy to reduce efficiency, very hard to increase it.

Quote from website:

"Solid wire instead of litz?: Keep in mind that the work described
here used close-wound 125/46 litz wire. If one duplicates 'Coil and
Former B' in Table 2, except using 22 ga. solid copper wire (having
the same diameter) as 125/46 litz, the Q values drop to about 1/6 of
the values achieved with the litz wire. The cause is the large

proximity effect resistive losses in the solid wire. The proximity effect, but not the skin effect loss may be much reduced if the wires are space-wound. New trade-offs now must be considered: Same wire diameter, and therefore a longer solenoid, or a smaller wire diameter and the same overall length? If one wishes to use solid wire, it should probably be wound directly on the ferrite, not on a former. The overall Q will still be much less than when using litz, but the loss from the high (tan δ) dielectric of the ferrite will be pretty well swamped out because of the now higher losses from the skin and proximity effect losses. The Q values, using a close-wound solenoid of 22 ga. solid copper wire on a polyethylene former, as in 'Coil and Former' B in Table 2 are: 520 kHz: 130, 943 kHz: 141 and 1710 kHz: 150 when using the "best core". The Q drops only 3, 3, and 5 points respectively if the "worst core" is used. "

Hi David,

100 mW in the 2M region is enough power to communicate with the space
shuttle. You are not lacking for power, you are lacking for scale.
Your inspiration of 7+ Ghz comes close enough to be achievable (and
using Gunn Diodes as transmission sources). However, scale will still
make the product about as long as a pencil, or the entire structure
the size of a business card. Not quite the key fob, but closer.

>more on the dielectric material, physical diameter, and the size of the
>center conductor, than it does on the jacket material. Also, aluminum is
>a pretty good conductor anyway.

In order of importance, the size of the centre conductor contributes most to losses, followed by the outer shield and the dielectric.

This is simply because the centre conductor is smallest. It carries the same current as the shield; but the current *density* on the centre conductor is several times higher. RF current flows only on the surfaces - the outside of the centre conductor, and the inside of the shield - so it works out that the resistive losses are proportional to diameter-squared.

Because losses in the shield are much less important, a small increase due to using aluminium will have almost no effect on the overall cable losses. The problems with aluminium-shielded coax are almost entirely about corrosion.

Dielectric losses don't come into this at all, because they are only a small part of the overall cable loss (at least, for frequencies up through UHF). "Low-loss foam" is simply marketing guff. When someone designs a lower-loss version of a standard cable, it has to start with a larger centre conductor - because that is the only change that *really* makes a difference. A foamed or semi-airspaced dielectric is something the designer was *forced* to use, to keep the same characteristic impedance.

It is technically true that the dielectric losses are a little bit lower than for the same solid material; but dielectric losses aren't important anyway, so using foam makes almost no difference to the overall cable loss. The designer knows that... but at some stage the message switches

over to "low-loss foam", because that's what the managers, the company,
the industry and its victXXXXcustomers expect to hear.

Getting any kind of directivity at 150MHz with small aerials is very difficult. The wavelength at 150MHz in 2m so you can see that element lengths will be quite long. One possibility might be a ferrite rod type antenna if you can find some vhf ferrite. Some older pagers used them so that may be a source. However you may still struggle to get very good directivity.

Perhaps an active solution may be a better bet. Try Googling for Handifinder, which is basically 2 small antennas that are switched at a fast rate, this produces a tone in the receiver which vanishes when both antennas have equal path length to the source.

Regards
Jeff

Cecil, I can understand the above paragraph ok, it is self defining
though so I don't consider it to be any great advance of the art.

Whilst I can understand the paragraph, the content is so trivial I can't
understand why you felt it necessary to state it.

Owen

I found that, when using a 2m handheld (Trio 2200, therefore both
hands!), using your body as a shield can be used to give a useful
indication of where the signal is coming from.

Hi, all concerned:

I have a CC A50-6S (20' boom), and enough CC 40M loaded elements to make a 2el 30M yagi.

1. Where do I start to model the two interlaced on the same boom, in EZNEC3?

2. If the interlace works, can it be stacked midway between a CC 402CD and a HyGain TH11 which are 12' apart?

Didn't say it was an advance. It is my position that
you questioned and it really seems obvious to me.

> Whilst I can understand the paragraph, the content is so trivial I can't
> understand why you felt it necessary to state it.

It was apparently necessary to get you to understand my
position. Wherever the circulator load resistor is
located is where the dissipation of the energy in the
reflected wave will occur. It can be either inside the
source box or outside the source box.

I disagree. The cable companies are changing out to foam filled cable
for good reason even if it is expensive.When a joint allows moisture
in it accumulates and cables that hang between poles sag such that
water collects at the center. This accumulation does make a difference
and the only correction is to replace that section.Fortunately the
foam used in cables are 'closed cell' which prevents moisture seeping
in.

I'm with you on this Bill. All of these measurments are unloaded Q.
Your not going to use it unloaded, so whatever Q you start with it will be
less in circuit.
I have many ferrite loopsticks and they all have Litz wire not solid wire.
The manufacturers spend the extra money for a reason.

I think Ben's loopstick work was done regarding use in crystal radio work.
The end result is driving a speaker with what little power is left after
losses.
Mike

Very interesting Bill but in a way the report appears to be distorted
to over emphasdise the advantages the author is declaring.To compare
the "best with the worst" is some what unusual. It would have been
better served if
average type ferrites were used and a smaller size former than that
chosen by the author. As a scientific paper it does a good job in
pointing out gains and losses between two aproaches but in real life
the differences appear to be over played. Certainly it brought up
things that had not previously thought about and I suppose the final
test of its merits depends pretty much on whether industry changes
over design for its A.M. radios and that the customer will be able to
discern advantages.. I may be wrong but it does seem to suggest that
larger ferrites are to be used
which avoids convention of small compact receivers, a much larger
negative

than any perceived advantage and the author has only emphasised
perceived advantages to enlargen the importance of his reseach.
However it was you that brought up the question in the first place and
now the supposed scientific report which begs the question what sort
of comments you were expecting from the group.

Cecil,

I understand the physics quite well, thank you.

What I neglected to fully pick up was the silly semantic game you were
playing. We all know that "power flow" is a bit of an oxymoron, but it

still is widely used as an equivalent to "energy flow". I was just trying to understand the phase of the moon in Texas for this particular thread.

You realise, don't you, that in a large parking lot filled with cars
(that's why you can't see yours - isn't it) you will be surounded by a
multitude of large RF reflectors?

Use your ears.
Honk the horn.
Your ears will be more directional than any
RF-with-tiny-directional-antenna-at-150mcs solution could be.

Or, get an amateur radio license and mount a large, honkin' 80M mobile
whip on it.
Use your eyes -- the *most* directional.

From your last posting it was not readily apparent
that you knew the difference between energy and power.

There is no reflected power wave but there is a
reflected RF energy traveling wave, the power of which
can be measured at a fixed point. A Bird directional
wattmeter indirectly senses the reflected power at the
fixed location of the Bird.

From: Jim Leder <k8cxm@fuse.net>
Message-ID: <bf16c$4607f9e9$d0660f9a$30070@FUSE.NET>
Source record: 44204

I am most likely going to buy a new Ameritron RCS4 antenna switch so I can not have so many coax cables coming into the house. Question: does anyone know if this switch shorts all the unused connectors to ground? How about when the switch is turned off?

Thanks

While I have no disagreement with everything else Ian stated, I do take some exception to the above comment about foam. Just take a look at RG-8 for example. With all other aspects of it remaining the same, there certainly is a significant difference in loss figures when the dielectric is changed from solid to foam.

Significance is in the eye of the beholder. At 400 MHz,
RG-8 foam seems to have a loss advantage over ordinary
RG-8 of ~2 dB per 100 feet. At 10 MHz, it is ~0.2 dB.
Is that significant?

You can download the manual here:

http://www.ameritron.com/products.php?prodid=RCS-4

The schematic does not show any grounding for the unused ports, nor
does the word description. Hope this helps.

Hi Ed,

Actually, all other aspects do not remain the same when you go from
one dielectric to the other.

The size of the inner conductor changes, and with it so does loss. The
loss is in the conductor, not the dielectric.

I have I think the RCS8, there are 8 positions but none were grounded.
I grounded the #1 position and everytime I shut down I would chose
position #1 and my coax would always be grounded

Richard, although it exhibits a mismatch, and thus detunes the source, the probability of the reflected energy
being absorbed by the source is zero. The additional power dissipated in the source is due to lowered
impedance of the network resulting from off-resonance operation, thus increasing the plate current. The
reflected energy does not enter the network, but only results in a decrease in the power delivered relative to
that when the reactance in the load is cancelled by correct retuning of the source network.

Twisting the knobs is what adjusts the output impedance of the network to the complex conjugate of the load.
But without this intervention the real probability of destruction by heat is not resulting from the reflected
energy reaching the plate--it is only that the reflected energy detuned the network, causing the plate current
to rise because the network is off resonance.

I think you are referring to the Times Microwave LMR cables. The LMR240 is sort of a low loss RG8X, and the LMR400 is a low loss RG213. These cables are made like RG6 in that there is 100% foil coverage bonded to the inner dielectric with normally a tinned copper braid over it. The aluminum versions of these replace the copper braid with aluminum braid. They claim the loss is the same because the bonded foil is the same. The only problem I see is soldering to the aluminum braid, and I suspect crimp on connectors will be easier to install. You can still solder the center conductor. Check out
www.timesmicrowave.com
BTW, the LMR240UF makes for great patch cords. It has a stranded center conductor. 1/4 inch cable that is rated at 1500W. The LMR240 without the UF suffix has a solid center conductor, costs about half as much, and I use it for longer runs below 30 MHz. Haven't seen any of the aluminum stuff yet.

Detailed specifications, please?

It is impossible to change only the dielectric and have literally "all other aspects remaining the same". If you want to keep the same characteristic impedance, at least one more thing has to be changed - either the centre conductor diameter or the shield diameter (or possibly both).

You might consider a Top Ten Devices switch. Six positions, full
grounding.

http://www.qth.com/topten/sixway.htm

Note that they also sell a weatherproof version of the switch

I see you are still confused. Waves flow. Power doesn't
flow. Energy flows. Does your Bird wattmeter move while
it's indicating power or does it stand still while
indicating joules of energy passing a fixed point in
one second?

There is a market for lower loss cables that are of similar dimensions to existing cables like RG213 and RG58. In my experience there are a range of cables with the same outside conductor dimensions, foam dielectric and a effectively larger inner conductor. It is often stated that the foam dielectric give the cable its lower loss, whereas the mechanism at HF is that for the same sized outer conductor, the lower permittivity of the foam dielectric requires a larger centre conductor for same Zo.

For example, the k1, k2 factors for a loss=k1*f^0.5+k2*f model for two dimensionally similar cables are:

Belden 8262 (RG58C/U): 1.30e-5, 2.95e-10
Times Microwave LMR195: 1.17e-5, 1.54e-11

k1 is proportional to copper loss, and k2 is proportional to dielectric loss.

Looking at LMR195, the reduced loss at 10MHz is almost entirely due to the reduced copper loss.

It is not until about 2GHz that the dielectric loss in RG58 equals the copper loss.

The message to carry away is that an 'RG8 foam' cable may be manufactured with the same diameter dielectic and braid, but use a larger inner

conductor. Connector compatibility might be more about compatibiility with the inner conductor than the connector body.

Owen

none of them flow. electrons move, this is called CURRENT. a current
causes a voltage which is related to it by an impedance. that is all you
need to know. power flow, energy flow, birds flying, those are all
secondary effects calculated from the fundamental elements of current,
impedance, and voltage. nothing else is necessary, everything else is
confusing since important details get lost when most people do calculations
of power or energy. stick with the basics and it will all become clear!

From the spec sheet, the average power rating at 30MHz is 1240W. I assume that is with VSWR=1, so that a further derating is required for mismatch. For example, at VSWR=2, the heating at a current maximum is nearly double that for a flat line, so the power rating might be more like 620W with VSWR=2.

Of course, in SSB telephony, the average power is very low and the cable is probably limited by voltage breakdown at peaks, specified as 5.6kW for LMR240UF.

I have a old 2 piece hollow 11 ft surf rod in the shed and need a mobile antenna and a sand flag on my Jeep Wrangler. I thought I would be able to do both with the fishing rod.
Question 1. How much minimum wire would I need to load it up on all Hf Freqs (I have a tuner).
Question 2. Could I bottom load it with a coil?
It would be connected to the tuner with RG 58 coax (about 10 ft).

Hi Walt,

Examples of separable energies in lines abound. We needn't have to go into circulators, isolators, directional couplers (the real ones, not the Bruene variety) and the rest, which all exhibit classic separation to achieve many design goals. Hence, it follows that reverse energy is real. The longer you pour energy into a mismatch, the longer it will reflect it back. Longer brings time into the discussion and hence power. Power is directly correlateable to heat.

Now, the amount of heat is directly correlateable to phase relations. If they are aligned at one of the cardinal points, heat will drive up. If they are aligned at the other cardinal point (180 degrees away) heat will fall. Heat is positive proof of resistance. Being hot or cold is sensation, not heat per se. That is, if the source cools, this is not proof of the source not exhibiting a source resistance - phase does not create nor diminish resistance. Or to put it another way, source resistance is not a function of phase.

There is a continuum of phase relationships expressed in angles between 0 and 360. Half will tend to heat, half will tend to cool. Energy is dissipated for the full 360 degrees.

When that reverse energy arrives by transmission line, it sees a load. Complex as it is, it must resolve to find itself within this continuum of response. Examples of plate incandescence or arcing are not trivial parlor tricks. You can force the situation with a lumped equivalent, but a lumped equivalent will not prove any invalidity of

the transmission line model it replaces (which, on the face of it, is an ironic appeal). This can be simply proven in that a lumped equivalent does not exhibit ALL the characteristics of energy storage in a long line.

Some (others than you, Walt) may be tempted to trot out the ghosts in the TV line proof. That is certainly one characteristic that a lumped equivalent can never exhibit (and yet the equivalent acts like the line to an amazing degree for many considerations). No, I won't delve into the endless debate about transient vs. steady state. This is an argument about as insipid as can be offered (by others than you, Walt) as if it made any difference. Rather, a resonant line will exhibit identical properties of resonance at harmonics - a lumped equivalent will not. It is quite obvious that a lumped equivalent is not wholly equivalent, except for a highly constrained example. To say (by others than you, Walt) it supports a general solution that invalidates the line's reality is as absurd a notion as any that are trotted around the track here. In short, if a line exhibits itself as a source of energy for any example, no equivalent can negate that physical truth in a proof for other use.

Hence, it follows that:
1. reflected energy is real and consequential;
2. sources exhibit resistance to energy flow;
3. 1 & 2 combine by their phase to result in a change of heat - dissipation;
4. the operator of either a tube or transistorized rig can adjust the phase of 1 through the intermediary of tuning (or conjugating);
5. absolutely no intervention impacts 2, except by degree;
6. successful/unsuccessful intervention still proves 3.

Good mornig all,

I'am happy to present you "Antenna Search", a search engine dedicated to the antennas of any nature.

http://www.les-antennes.fr/

Antenna Search is actualy a beta version, but seems to work correctly.

Best regards,

Oli

Sorry Dave, the essence of an EM wave is its electromagnetic
energy. Voltage and current are the secondary effects of
the photons encountering a conductor. What happens when one
doesn't have a conductor?

What's the voltage and current in the light from Alpha
Centauri? Optical physicists have known for decades what
is the essence of EM waves and they don't use voltage and
current except for some esoteric calculation.

I wish somone would convince my boss reverse power isnt real. Then he wouldnt be so angry about the power meter head I blew up because I forgot to put an attnuator on it. Even with the -20db of the coupler ther is still 20 watts peak on the reverse side.

Power waves are respectable but a writer chooses his own words.

Searching the web on topic: "power reflection on mismatched line" yielded 12,778 hits. First two were from the physics department of the University of Queensland in Australia. No qualms about the word "power" are shown and sample problems are worked. Here is one statement: "Note that the power reflection coefficient is equal to the square of the voltage (or current) coefficient because forward or reflected waves are in rhe same impedance."

Remarkable or not, that is the seesnce of what the Bird Electronic Corporation says in instructions for its "Thruline Wattmeter".

Power is acceptable and accepted. Why avoid the term?

Walter Maxwell, W2DU wrote:
"When the matching is accomplished the phase relationship between the forward and reflected voltages can either be 0 degrees or 180 degrees, resulting in a total re-reflection of the voltage. If the resultant voltage is 0 degrees, then the resultant current is 180 degrees, thus voltage sees a virtual open circuit and the current sees a virtual sees a virtual short circuit. The result is that the reflected voltage and current are totally re-reflected IN PHASE with the source voltage and current. This is the reason the forward power in the line is greater than the source power when the line is mismatched at the load, but where the matching device has re-reflected the reflected waves."

Eloquently stated and significant because there are many who would swear that a properly matched transmitter re-reflects the reflected waves, but don`t have a clue as to why.

If reflected power wasnt real I wouldnt be in trouble or at least on the
shame list. I picked up 30 db pad to put on the pwer meter some body
started talking to me and I forgot to put the thing on before I took the
reading. In other words my origional reply was a kind of tongue in cheek
raz to anyone who doesnt believe reflected power is real.

Actually, significance is based on the frequency of operation, as you
just indicated. Since the original poster was talking about an aluminum
jacketed heliax, I assumed the pertinent frequencies to be at least VHF,
if not higher; which would make the difference between the foam dielectric
RG-8 and solid dielectric RG-8 signifacant!

I will eat my words! My previous experience has apparently been
comparing apples and oranges. I just compared Belden 9913 with 9914...
the only real difference between these two being one has a solid
dielectric and the other a foam dielectric.... the loss differences were
basically non-existant!

Sorry for all the bother!

Regarding Question 2, absolutely! Personally, that's the way I went with a similar project. I took much pleasure in reading Nylo's website at:

http://www.qsl.net/n1lo/mobilhf.pdf

Also, plenty of information in the handbook, and if you have a recent copy of the handbook, (or was it the ARRL Antenna Manual?), the disk in the back contains a little ARRL program called "mobile.exe" which would be right up the alley for your project. Good Luck.

Richard Harrison wrote:
> Power is acceptable and accepted. Why avoid the term?

Jim Kelley, AC6XG, has convinced me to make the
distinction between the nature of EM energy and
the nature of EM power. Power is what exists at
a point or plane. Energy is what is moving past
the point or through the plane. Reflected power
is measured at a point. Reflected energy is
what is doing the moving past that point.

In addition, there's the difference in definitions
between the fields of RF engineering and the field
of physics. In physics, zero work implies zero power.

I am not avoiding power. I am avoiding "power waves"
and "power flow". The dimensions of power flowing past
a point would be watts/second. I don't know what physical
quantity that would represent.

I'm moving to a new QTH and have only kept up
with this thread sporadically. I have now gathered
that the point is that it's not the foam per se
that has the largest effect, but the larger center
conductor required to bring the impedance back
to 50 ohms. Consider the fact that the 9913 center
conductor is #10 while the RG-213 center conductor
is #12.

Oh, and don't forget to correlate that angle to include the effects of
local objects, terrain, and other variables so that everyone can
construct THIER antennas to match the ascetic ideal of similarly
aligned angles of radiation

I brought up the question before I found the website which was
provided by someone from another group <sci.electronics.basic>

Another glaring error pointed out was the bandwidth limitations using
a high Q coil. As the Q goes up, the bandwidth goes down to possibly
unusable values. At 800Khz and a Q of 1000, the bandwidth is only 400
Hz. Not very good at audio frequencies.

I think the answer is to use as high a Q as possible and then
load the antenna coil so the Q falls to the desired value. It's easy
to drop the Q, very hard to increase it.

Thanks,

-Bill

Art wrote:
"Any thoughts as to why it sgould be so and the scientific facts to support it?"

We have plumb lines and bubble levels which allow easy determination of vertical and horizontal directions.

We often inhabit a nearly horizontal plane

If we are as likely as not to communicate with any particular direction, an omidirectional vertical antenna makes sense. An inclined wire would favor some direction to the detriment of another. Sure a slopimg wire works but doesn`t reach maximum height or length as effectively as a vertical or horizontal wire would.

Why a straight dipole and not a V-shaped element? The V-shape corrupts the nulls at the ends of the straight wire.

Vertical and horizontal antennas are not solely accidents of history.

Best regards, Richard Harrison, KB5WZI

>I'm probably going to want DX, though, so NVIS isn't something that I'm
>seeking. If I'm horizontal, I'll want some elevation.

The NVIS was not caused by the hamsticks, themselves,
but by their being VERY LOW!
(2 feet above my pickup cab is only 8-9 feet high)

I'm not in any way claiming hamsticks are the "best" antenna,
but if you elevated a dipole made of them, I'm sure they
would not act like cloud-burners anymore.

>to 50 ohms.

From the designer's point of view, it was the other way around: centre conductor first, dielectric constant second.

The boss says: "We want a lower-loss coax, in the same outline as RG213 and still 50 ohms."

Starting from RG213, the first thing the designer does is increase the diameter of the centre conductor, because that's where most of the losses come from. He now has a lower-loss solid polyethylene cable that will fit an RG213 connector body, but has an impedance of around 40 ohms.

>Consider the fact that the 9913 center
>conductor is #10 while the RG-213 center conductor
>is #12.

Just so.

To bring the impedance back up to 50 ohms, the designer then has to reduce the dielectric constant, by using either foam dielectric or a semi-airspaced construction such as 9913. The losses do reduce a little more in the second step, but not much.

As I said yesterday, the third step is that Marketing gets hold of it... and that's where it all turns into foam.

Richard Clark, KB7QHC wrote:
"There is a continuum of phase relationships expressed in degrees
between 0 and 360."

We are discussing transmission lines and assuming near perfection.
Indeed the phase of the wave depends on that of the generator when it
was launched and the phase of the generator continues to advance with
time, but a good line enforces its Zo, a resistance.

Terman says on page 85 of his 1955 opus:
"The incident wave on the transmission line can therefore be described
as a voltage accompanied by a current that is everywhere in phase with
and proportional to, the voltage and dropping back uniformly in phase as
the load is approached."

The transmission line treats the wave reflected from a discontinuity
exactly the same as it does the incident wave.

The reflected wave is identical with the incident wave except that it is
traveling toward the generator.

At an open circuit or high-impedance load, there is tto much line
current for the high-impedance to accept gven the limited voltage. The
surplus current must reverse phase and the wave must travel back toward
the generator. There is no change in the phase of the voltage.

At a short circuit or low-impedance load, there is too much line voltage
for the low-impedance to accept, given the limited current. The surlus
voltage must reverse phase and the wave must travel back toward the
generator. There is no change in the phase of the current.

There are two phasing conditions between the voltage and current on an
ideal transmission line, 0 degrees and 180 degrees.

Best regards, Richard Harrison, KB5WZI

Found some Tables of loss and power handling for various cables. At 30 MHz:

LMR240 has a max power of 1490W, compared to RG213 of 1800W.
LMR240 has a loss of 1.3 DB, compared to RG213 of 1.2 DB.
Not a whole lot of difference, but the 213 has about 3X the cross section
area. The LMR240 has 90 DB shielding, the 213 is not specified.

I assume that these were specified under the same conditions. It is
interesting that at 900 MHz, the LMR240 has less loss than RG213. Compared
to RG8X, the 240 has 4 times the power handling capacity.

Cecil,

Utter nonsense. Jim was pulling your chain, and I guess you fell for it.

I have been a professional physicist for nearly 40 years. Real physicists fully understand the difference between power as work and power as energy transport. Both definitions are used as needed. I would hazard a guess that most engineers understand and use both definitions as well.

All of your ramblings about the difference between energy and power, as well as joules and watts, add nothing but noise to the discussion. It is highly likely that everyone reading this group understands the concept of time.

3133. Spacing and Element order for 6 element 10 meter yagi

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-27 16:13:27 UTC
From: Dennis Klipa <klipadk@gmail.com>
Message-ID: <1175012007.125291.39320@e65g2000hsc.googlegroups.com>
Source record: 44149

I have a disassembled 6 element, 10 meter yagi made by KLM, which is probably Model KLM 28-30-6. Tjhe elements are assembled but removed from the mast. I can pretty much tell where the elements go based on the marks on the mast but it isn't at all obvious which elements go where. Most beams have the longest element as the reflector and the shortest element as the last director. This beam appears to have two drivent elements. The driven element with the balun attached is the shortest of the six! The second driven element is connected to it by two lengths of aluminum flat stock, 40 inches between bolt holes.

Can anyone tell me the element order and spacing for this beam?

The stats are as follows
Boom: 29.5'
Elements:
219.5" or 18' 3.5"
200" or 16' 8" Second Driven Element (40" separation
from 1st)
191.5" or 15' 11.5"
187" or 15' 7"
183.5" or 15' 3.5"
171" or 14" 3" First Driven Element
Ferrite Balun Model # 3-60-4:1
The balun has KLM embossed on both endcaps

Thanks
Dennis Klipa, N8ERF

Gene Fuller, W4SZ wrote:
"Utter nonsense."

Cecil knows as well as anybody the difference between energy and power,
Power is the rate of doing work. The electrical unit is the watt
(joule/second). It is also the rate of transmission from source to load.

A wattmeter keeps track of the rate of energy flow, and the watt-hour
meter measures the integral of active power during the integration
interval.

The power company bills you for the energy consumed during an interval
determined by successive watt-hour meter readings.

Best regards, Richard Harrison, KB5WZI

Lamont,
Thanks for the lead. I placed an order with them but got a odd web page response after I placed the order. When I tried to call the voice phone number on their web site I got a "phone company recording". Do you know that this is a legitimate business? I did a Google search and found a number of references to the company so I am assuming it is but the responses I got make me a little nervous. I did a reverse look up on the address and got a name and phone number. Looking at the address on Google Earth, I see what looks to be like a UHF yagi on the roof, so I did a reverse lookup for a call sign at the ARRL sight and found the call for the name.

I am probably just being paranoid, but I have been burnt before.
Thanks again for the lead.
Dennis

How would you mount, insulate a surf rod? Seems it would be
easier to just scrounge up an old glass whip antenna, and modify
it. It will fit the usual threads for antenna mounts.
I have a couple of those that I have built, and both work all
bands. But mine are center loaded, not base loaded.
I strip all the original winding from the glass whip, and then
wind a new larger coil bugcatcher style.
The one I usually use is a 6 ft glass whip, which was originally a
20 meter hamstick. The coil which is appx 3 inches diameter,
and wound on a light plastic tube is just below the tip at the
5+ foot level. I then clamp a 5 ft stinger whip to the top of the
glass whip. The antenna is 11 ft tall total, and exactly center
fed. I also can use a 3 ft hustler mast at the base and the
antenna is 14 ft, and the coil at 8 ft+. I only do that parked.
I change bands the same way you would a bugcatcher by
tapping the coil, and I can also go higher in freq by using a
shorter stinger.
My original all band antenna was basically the same, but it's
total length is 10 ft, and was built on a 5 ft firestick CB antenna.
It's coil is 2.5 feet above the base. I still use it if I want the
coil
lower for tree purposes, etc..
Using a tuner to load a mobile whip is about the last way you
want to go. On most lower bands, max current will be at the
tuner coil. No bueno.. A base load would be better, but a
center load gives much better current distribution and efficiency.
Thats why my newer antenna has the coil higher, and also
is why I often add the lower mast when parked. That extra
3 ft below the coil really gives the efficiency a good boost
when on the lower bands. My coil is at the level some other
antennas tips would be.. :) In most cases, my antenna will

thrash those.. I've done it a few times on "park and compare"
tests.. I once compared against a usual hustler setup on 75m.
I almost felt sorry for the owner, who is a friend of mine. :/
That hustler was a dummy load on a stick...

3142. GFCI problem when running high power

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-27 18:27:28 UTC
From: "John, N9JG" <john@Xremove.MeYgotwals.com>
Message-ID: <kmdOh.18250$G23.8609@newsreading01.news.tds.net>
Source record: 44158

I am using an Orion to drive my Drake L-4B, and I operate mostly on 40 meters. My antenna is a 110 feet long dipole, center-fed with open-wire feed line, and elevated about 30 feet with the support for one end attached to the house chimney. My shack is in a 2nd floor bedroom, and the circuit breaker panel is located in the basement at the opposite end of the house. The house has a brick exterior, and one end of the antenna is only a few feet from the shack.

When I operate high power on 40 meters, a GFCI equipped circuit breaker, which is located in the house circuit breaker panel, moves to the open position. None of my station equipment is attached to this breaker; this particular breaker powers four outlets in the garage and two outlets on the house exterior. None of these outlets are normally in use. Is it possible (or even desirable) to install one or more bypass capacitors inside the breaker panel, and immediately adjacent to, the ground-fault circuit interrupter? If so, what type of capacitor is recommended?

I am using the MFJ-1124 DC Power Outlet strip, and its quality is quite good. I am contemplating the purchase of one of their line noise meters to help me locate one or more line noise generators, which are a big nuisance at my location. Maybe someone can make some comments on the MFJ-856 or MFJ-852 noise finders.

A GFCI measures the common mode current flowing on the "hot" and "neutral" conductor combination, and is designed to trip quickly when this exceeds a small, set value (indicating that the individual currents on the two conductors are unequal). And common mode current is just what your signal is inducing on those wires. What you need to do is block the common mode RF without upsetting the detection of common mode 60 Hz AC. What I'd try is to clamp a ferrite core over the combination of black and white wires on each side of the GFCI. A single pass through most of the common ferrite cores should have a very low impedance at 60 Hz, so shouldn't inhibit normal GFCI operation, but would add significant impedance to the common mode RF. I've never had to do this, though, so it would be interesting to hear from people who have had to deal with this problem.

In my considerable experience, it's a mixed bag. I like my 993B automatic tuner. I also like my 784B audio DSP filter. The 1026 noise canceller came with a flaky connector for the whip but it does work as advertised. The 931 artificial ground is a bit fragile and needed to be repaired after getting it second hand (the wire had come off the capacitor inside due to a cold solder joint breaking from shipping vibration). And I LOVE my 259B analyzer. It has saved me lots of trouble and trial and error.

I also have a nice little magnetic field strength indicator which is nice for spotting antenna currents on house wiring and feedlines. I forget the number and it's too far to run and look.

We used to use their basic keyer for commercial CW at Halifax Coast Guard Radio during the last phase of Marine CW there. They weren't complicated, had no fancy memories or anything, but worked day in and day out.

> that can
> contribute other than empirical grounds? You have avoided the question
> so far

Hello Art,

Radiation from accelerating charge is fully understood (from theory and verified practically), hence antenna theory. When you take the complete formula for fields (near and far) generated by a short wire segment (hertzian dipole), you can calculate the far and near field (magnitude, orientation, phase, etc) from every construction. The only problem is that you have to know the current distribution in your construction.

It is not of interest whether the charge is excited by just a voltage source or EM radiation (like in reflection of waves on conductors and dielectrics). This is done in many FEM programs.

Of course in many practical circumstances it is easier to use the "laws" from other people (that are derived from basic theory). One of the results are the Fresnel formulas for reflection.

When you know the properties of the soil at the operating frequency, you can calculate the complex surface impedance and hence the complex reflection coefficient.

Just mentioning words as "curl", "vector", "Gaussian" etc, doesn't make sense without further information.

Best Regards,

Wim

Why not, due to the close range, think inverse square law instead of directivity? Could still be a bit confusing in an underground carpark, but basically, the source and the receiver are close enough that a few steps ought to make a readable difference in strength. Just walk in a circle and keep widening it on the side where the signal is strongest and narrowing where it is weakest. The closer you get, the less sensitivity you need, so have some method of turning that down. And 100mw is LOTS of power for this!

The most likely explanation is that you have large RF currents in the power wiring of the house, due to some combination of common-mode currents on the feedline, and/or direct coupling from the hot end of the doublet into the house wiring in the roof.

Those RF currents will then flow to ground through the power wiring. At the same time they will couple into the live and neutral wires, and then flow through your GFCI in common-mode (roughly equal currents, in phase on both wires). Since most GFCIs have poor common-mode rejection at frequencies much higher than 60Hz, a substantial RF voltage can be coupled through to the inputs of the IC amplifier inside the GFCI - so it trips.

That is my best guess. To find out what's really happening, you need a clamp-on RF current meter such as the MFJ-854 (not the MFJ-853 - it's rubbish) or build your own from the information here:
http://www.ifwtech.co.uk/g3sek/clip-on/clip-on.htm
http://www.w8ji.com/building_a_current_meter.htm

IMO this meter is the ONLY way to see and understand where the RF currents are flowing. Then you can take steps to minimize them.

(By the way, you can almost certainly forget about an "RF ground". From a 2nd-floor shack it's almost impossible to provide a ground path that has a low enough impedance to shunt significant fraction of the RF current away from the mains wiring.)

> Is it possible
>(or even desirable) to install one or more bypass capacitors inside the
>breaker panel, and immediately adjacent to, the ground-fault circuit
>interrupter? If so, what type of capacitor is recommended?

Capacitors on the power wiring are the wrong answer anyway. Almost certainly, you need series chokes. K9YC's article about ferrite chokes and RFI is essential reading, and an article by W1HIS (although way over-the-top for most people) is full of practical ideas:

http://audiosystemsgroup.com/RFI-Ham.pdf

http://www.yccc.org/Articles/W1HIS/CommonModeChokesW1HIS2006Apr06.pdf
(or http://tinyurl.com/qnzs3)

Use the RF current meter to track down the power conductors that are carrying the largest RF currents, and then see what some ferrite chokes will do. Obviously the first place to try the meter will be on the various wires coming into the breaker panel, and that should give you a good clues about where the RF is getting in.

But almost certainly you should start applying chokes in the 2nd-floor wiring, and especially in the shack. Keep repeating the current measurements at the breaker panel to monitor your progress, but try to avoid making modifications there.

As W1HIS found, another reward for cleaning up RF currents on the house wiring is likely to be greatly reduced noise on receive.

Thanks for your comments and the link. A thought has just occurred to me
that perhaps I could damp out the rf energy in the unloaded wiring by
plugging a low wattage bulb (perhaps 5 watts) into one of the GFCI protected
sockets and see if that eliminates the problem.

Initially I had a small freezer in the garage plugged into one of the
sockets and some days later wondered why the freezer was no longer working.
At that time I discovered that the garage wall was also equipped with a
special non-GFCI protected socket which was installed by the house builder
specifically for a garage located freezer. After throwing out the spoiled
food and cleaning the freezer interior, I moved the freezer and plugged it
into the proper socket.

John,

If the GFCI is indeed a breaker, as you said, then you will not be able to access the line side of the hot wire. That connection will be from the back of the breaker to a bus bar in the panel. You should still be able to apply a ferrite core to the load side. Most breaker-type GFCI units will have connections for the black and white load wires close together on the end of the breaker.

Hi John,

The quick answer is that anything that
will reduce common-mode currents on the
branch wiring will be a move in the
right direction. At 60 Hz, the GFCI is
supposed to trip at 5 mA. At 7 MHz, who
knows?

Some experimentation may be in order:
why not try ferrite beads on the wires
near the GFCI. Remember that common-mode
currents may enter the GFCI from either
direction. High-quality capacitors rated
for the voltages involved would work too
but seem like a less elegant solution.

If you do go with the caps, you can do a
test by plugging them into the outlets
not normally in use: a quick and dirty
approach that makes no permanent change
to the wiring. Be safe, of course.

Here's a link that talks a little about
this:

Hi Richard,

This is, of course, contingent only when the line is terminated in its characteristic Z. Otherwise, given the premise of this thread, that is not true. However, you do amend by:

>The transmission line treats the wave reflected from a discontinuity
>exactly the same as it does the incident wave.
>
>The reflected wave is identical with the incident wave except that it is
>traveling toward the generator.

However, this presumes one of those one or two degree (0 & 180) solutions originating from either a short or an open that you explicitly introduce.

>There are two phasing conditions between the voltage and current on an
>ideal transmission line, 0 degrees and 180 degrees.

Actually, there are 360 degrees to consider, of which 0 & 180 make up slightly more than 0.5% of the complete picture. The length of the line presents this continuum to the unmatched source, and the source suffers by degree of phase relationships.

The solution to this perceived suffering, of course, is to introduce a match. This serves two functions against a mismatched load:
1. Delivery of optimal power;
2. Reduce the risk of added heat burden to the source.

> at the same time.
[snip]
> If reflected energy is not dissipated, it undergoes destructive
> interference and is redirected back toward the load as constructive
> interference instead of being incident upon the source.

I like these two paragraphs. They describe exactly what
I would expect the relationships to be were "reflected
energy" to represent real energy.

More importantly, they describe an expectation that
is sufficiently precise to be falsifiable.

But just to be sure I understand the meaning, let me restate
them algebraically:
Energy.reflected = Energy.dissipated + Energy.re-reflected

If this is not what you meant, then please read no further
until you correct my misinterpretataion.

Oh good. The interpretation is accepted. So let us call
this "Cecil's Hypothesis":
"If reflected energy is not dissipated, it is redirected
back toward the load."
Expressed as an equality:
Energy.reflected = Energy.dissipated + Energy.re-reflected
And for convenience, its power form:
Preflected = Pdissipated + Pre-reflected

Now all we need is a single example for which the equality
does not hold and "Cecil's Hypothesis" will be disproved.

Let us start with the example previously offerred:
- Generator with 450 Ohm output impedance
- connected directly to a 1000 foot line with 450 Ohm
characteristic impedance
- connected to a load with 75 Ohm input impedance.

And to simplify computation and produce a numerical result, we add a few more details:
- The generator is 2 Amp current source in parallel with a 450 Ohm resistor
- The line is 31 wavelengths long

Let the experiment begin:
- The generator is off.
- All currents, voltages, energies and powers are zero.
- Turn on the current source.
- The current source pushes 2 Amps.
- This is divided equally between the 450 Ohm generator resistor and the 450 Ohm line.
- The generator output voltage is 450 Volts.
- The generator output current is 1 Amp.
- 450 Watts is being put out by the generator
- 450 Watts is being dissipated in the generator resistor
- A real wattmeter (one that measures voltage and current) shows 450 Joules/s flowing down the line. (Is it okay to say that "450 Watts are flowing"?)
- A directional wattmeter indicates that the "forward power" is 450 Watts and the "reflected power" is 0 Watts.
- Vfwd is 450 Volts
- Ifwd is 1 Amp
- The load is happily oblivious to the oncoming onslaught.
- 31 cycles later, the voltage, current and energy reach the load.
- But there is an impedance discontinuity which creates a voltage reflection coefficient of -0.714 so the load refuses to accept all the incoming energy.
- The voltage across the load is 128.6 Volts
- The current into the load is 1.714 Amps
- The power dissipated in the load is 220.4 Watts
- Vref is -321.5 Volts
- Iref is 0.714 Amps
- Vfwd is still 450 Volts (the line is lossless for this example)
- Ifwd is still 1 Amp
- "Forward power" is 450 Watts
- "Reflected power" is 229.6 Watts
- 220.4 = 450 - 229.6 which is as expected and demonstrates the usefullness of a directional wattmeter for computing actual power transferred (or is it energy?).
- Encountering the reflection has caused a change in the voltage and current and this change is now propagating back towards the generator.
- 31 cycles later, this change in line conditions reaches the generator.
- The conditions at the generator terminals are now the same as the load since it is an integral number

of wavelengths from the load.
- The voltage at the generator terminals is 128.6 Volts
- The current out of the generator is 1.714 Amps
- The "forward power" is still 450 Watts.
- The "reflected power" has changed from 0 to 229.6 Watts.
- There is 128.6 volts across the 450 Ohm generator resistor.
- There is 0.286 Amps flowing in the 450 Ohm generator resistor
- Because the 0.286 Amps in the 450 Ohm generator resistor plus the 1.714 Amps flowing into the line is 2 Amps, exactly the output of the current source, the system has now settled after one round trip. There is no re-reflection at the generator terminals (and no ghosts).
- The power into the line is 220.4 Watts
- The power into the 450 Ohm generator resistor is 38.6 Watts
- 229.6 Watts of "reflected power" has reduced the dissipation in the generator resistor by 413.4 Watts.
- Substituting into the hypothetical equality
Preflected = Pdissipated + Pre-reflected
229.6 = -413.4 + 0
- The equality does not hold, thus disproving "Cecil's Hypothesis".

It is instructive to also consider the case with a generator constructed as a 900 Volt voltage source connected to a 450 Ohm output resistor.

In this case the 450 Watts dissipated for the first 62 cycles increases by 872 Watts to 1322 Watts when the reflection arrives. Similar to above there is no re-reflection or ghosts.

Once again the hypothetical equality
Preflected = Pdissipated + Pre-reflected
229.6 = 872 + 0
does not hold.

But the principle of "conservation of energy" should hold whenever real energies are involved.
Since it does not hold in this case, we can only conclude that the numbers computed for "forward and reverse power" do not represent any real energy flows but are merely conveniences to facilitate other computations.

...Keith

3159. Re: Best Yagi impedance

Newsgroup: rec.radio.amateur.antenna

Some comments on the 25-35Ohm range for the impedance of Yagis, which has VE2PID from my website. Without further details this makes indeed no sense to say this would be the best for Yagis.

1. You must differ between short Yagis and Longyagis.
2. You must know for what bandwidth the Yagis should be designed.
3. A given result you can reach with a nearly infinite number of changed parameters.

For short Yagis and the bands 14-1,35MHz, 21-21,45MHz, reduced 10m-Band from 28-28,8MHz, and for 144-146MHz a low impedance (10-15Ohm) does not cover the entire band, but gives high gain. A high impedance with 50Ohm gives away to much gain for a to high bandwidth. For example a 3-Element-Yagi with 50Ohm direct feed cannot reach more than 5,5dBd. The reasons therefore are pointed out by Roy, W7EL in his comments about element coupling and element currents.

For the enumerated bands the impedance of 25-35Ohms is indeed the best for a good balance of gain, pattern and bandwidth. By adding a close spaced D1 for 50 Ohms you can reach similiar results, but why doing that? For more weight and additional mechanical problems?
It is better to match the impedance to 50Ohm than to add more elements for rising the impedance!

For Longyagis the problems are more difficult. You must see the radiator, D1 and D2 as a unit (radiation center) in a Yagi system. The very close spaced D1 in a 50Ohm-feeding system acts like an "open-sleeve-element" and has higher currents than the radiator. The interaction between these elements can reduce the bandwidth dramatically, because -j and +j of the impedance increase very fast if you leave the center frequency.
It is interesting but a fact: You can replace the 50-Ohm-radiator and a close spaced D1 in several Longyagi systems by one radiating element with lower impedance and greater bandwidth.
Evolutionary algorithms for optimizing Longyagis find more lower impedances than 50Ohm for a given gain, pattern and bandwidth. The matching "by hand" with the close spaced D1 (as Ian, G3SEK writes) in the finishing construction process is possible but no must.

I think GFCI refers to a breaker that operates on a small imbalance of current on the active and neutral wires (or whatever you call them) of the AC distribution. Typically, such things operate on quite small current differential (30mA for standard devices in our part of the world) and with fast operate times (~20mS). To perform this function they use electronics to amplify the current difference from a current transformer, and operate the breaker trip magnet. The electronics is usually powered from the AC line. Do not overlook the potential for RF interference with the electronics, although they should be designed for electromagnetic compatibility, your switch may be susceptible to the levels that occur on its AC line terminals.

Others have addressed whether the switch is responding to differential RF currents. My guess is that it is less likely that the above, but that is only a guess.

If that is the problem, remedial measures include replacing the switch preferably with a different brand (though that might not fix the problem), changing your station arrangements to reduce the RF on the AC distribution (which could be coming from supply or load side of your

breaker), filtering on the power lines (again this may be effective if located on the supply or load side, but you might be limited in what measures you can employ easily on the supply side).

Owen

All in all their quality is OK I guess. I have the MFJ-401D keyer,
MFJ-564 paddles, MFJ-1026 noise canceler, and MFJ-921 VHF antenna tuner.
They all look like something that a really talented homebuilder could
build in his home workshop, and they all work more or less as advertised.

What really bugs me is their insufferably arrogant attitude about
providing support via email. On their support page they say "There is a
two to four WEEK (emphasis mine) response time for support emails and if
that's not good enough for you, call us on the phone". There is no excuse
for that kind of an attitude.

Do you mean:

Do they still use thermoplastics for coil supports and roller inductors so that the components are damaged if they get hot?

Do they still leave loose bits of solder, wire, nuts etc inside completed euipment?

Do all their instruments that claim to indicate PEP power actually work on SSB telephony?

Do the meters on MFJ antenna analysers still fall into the case if you make the mistake of gripping the analyser with thumb pressure on the meter?

Do they still use hard-to-get incandescent lamps to light meter movements?

Do they take a month to respond to spare part enquiries, and then make a partial response that is of no use?

Do they still use plated steel parts that don't withstand weather for more than a year or two on their antennas?

Do they still ship linear amplifiers with a circuit diagram that is so shabby, it defies unambiguous interpretation?

Are they still buying up other manufacturers to apply their "quality" to the whole market?

Art wrote:
"I have his (Kraus`) second edition (Antennas) and I find no mention of radiation from the beginning where current is applied onward."

I think I have that edition too. If you review the chapter on "Point Sources" you`ll find: power patterns, a power theorem and its application to isotropic sources, rediation intensity, source with hemispheric power pattern, unidirectional cosine power pattern, etc., etc..

The new, now available 3rd ed. of "Antennas" by Kraus, Marhefka, and a host of others is greatly expanded and improved. It is worth the investment.

Being uncertain of what Art really wants, doesn`t stop me from advising him to start by having a look at the famous Sommerfeld formula on page 804 of Terman`s 1955 opus.
It predicts 1 kilowatt will produce 186 mv per m at a distance of 1 mile from a short vertical transmitting antenna given a certain ground conductivity and other conditions.

Thanks mk, I was going to turn a base for the rod and mount the coax connector on the outside of the area where the reel is fastened as it is hollow and then fix the base two small muffler clamps to the bullbar.
As you state centre loading is the go and can be done with this rod as it is a two hollow glass rod.

Richard Clatk, WB7QHC wrote:
"This is, of course, contingent only when the line is terminated in its characteristic Z."

Lines terminated in Zo don`t produce a reflection at the load. I did not make up the fact that the line forces the current to be exactlly in-phase or exactly out-of-phase with the voltage across the transmission line. I got it from Terman. On page 86 of his 1955 opus: "---This differs from Eqn (4-8) (Zo seen by the incident wave) only by the negative sign, which arises from the fact that the current in the reflected wave travels toward the generator whereas the current in the incident wave travels toward the load.

Zo is a RESISTANCE. In a resistance, current is in-phase with its associated voltage. Waves traveling in either direction on a line see the same Zo.

Lamont,
That is very reassuring to hear.
I am sure it will all work out just fine.

Thanks,
Dennis

Hi Richard,

You've missed the point of Art's pining "why?"

Explain how the conductivity of ground forces some polarization issues
- you know, the basic stuff of propagation.

Art wrote:
"Could you quote from the books that you are referring to the angle relative to the radiator, that`s it?"

O.K.. but the angle is relative to the horizontal in the statement. Termans 1955 opus on page 804 says the strength of radiation from a short vertical antenna is proportional to the cosine of the elevation angle. That`s right because at zero angle, radiation is maximumm as cosine of zero degrees is 1, and cosine of 90 degrees is zero.

I may be able to respond to a question, but I don`t write books.

On the question of ground conductivity and polarization: Soil loss makes vertically polarized waves tilt forward in the direction of their travel as if dragging their feet. It`s not all bad as this tilt makes a horizontal antenna, the Beverage, receive these vertically polarized waves well.

I have about ten of their products. Most are fine. My best advice is
to buy from a retailer that will take the product back in a few days
if you don't like it.

I'd stay away from their current tuners. An older one I have, a 989C,
is good stuff. A newer model, the 989D was junk and promptly returned
to Amateur Electronic Supply.

Bingo
Just as I thought, you are bullshitting like the rest of them. All you
have is the answer for the question you want me to ask so you can then
look good.
When you give that same answer to any question that I actually ask it
sure removes any possible credability.
If you all had been nice to the MIT guy he may have come back and give
you a tutorial again to set you straight, but I suspect he left for
the same reasons that other experts left. I accept that none on the
thread has a clue
so it is reasonable to close down this thread to allow you to get back
to badger Walt. I believe that each poster has provided an average of
ten posts
on Walt's article which suggest that Walt is having a bad time with
communicating his message like me. My bet is that half of the posts
aren't even relavent to the subject at hand! That's tough for
anybody.Richard you have posted four times with lots of words on this
thread but at the very end you admit that you have no idea what the
thread was all about. So what were your answers meant to apply to so I
can oblige you with supplying the question that you want... to the
answer you have already so you can spout off.
No ....forget it.
..........FINI.........

Jim,

I have the RSC-8V and the manual says that the unit comes with the
unselected leads isolated from ground. If you want them to be
grounded you have to install a jumper and it shows a diagram on how to
do it.

<withstand horizontal positioning > If I do this, I will have the thing laying on the roof, at or near the peak, so support won't be a consideration. (The far end of each unit could stick out and be self-supporting.) Having it slide down the roof is a bigger worry.

< vertical dipole> Ahah! I started out with a 10m vertical dipole as my first-ever HF antenna, last month. (It has since morphed into an OCF horizontal dipole that I've stretched all the way to 40m with a homebrew pi-network tuner I acquired at the swap meet.). To the point, two opposing trap verticals as a single dipole would be a 70 foot vertical structure and is not within my capabilities. (I would love to try it, though.)

Hi Cecil,

Dissipation and interference are not interdependent phenomena.
Moreover, destructive interference does not "redirect" or otherwise
cause anything to happen. Intereference is nothing more than a means
for describing the result of the superposition of waves.

We can agree to disagree on that one. I consider email to be a great telephone-tag eliminator, leaves a convenient written record of what was said, AND allows people to respond on their schedules rather than having to drop what they're doing, or sit on "hold" for who knows how long.

I consider their attitude supremely arrogant and utterly unnecessary. You don't have to agree, but you also don't have to disagree by name calling.

This'll be my last post on this...

Walt doesn't actually indicate 'why' here, either. He is reciting a set of well known circumstances, and implying that one set of facts results in another. While the facts are obviously correct, any cause and effect relationship between them must be inferred. It is not demonstrated. The fact that every time a visitor stands at my front door the bell rings is not proof that standing at my front door *causes* the bell to ring.

The behavior of electromagnetic waves and their interaction with matter as described by JC Maxwell and others already provides satisfactory and sufficient explanation for the phenomenon of reflectivity. That should not be overlooked here.

Cecil's hypothesis is that the conservation of energy
principle is valid. All you need is a single example for
which the conservation of energy principle does not hold.

Remember, the magnitude of energy in a transmission line
is *EXACTLY* the amount of energy needed to support
the forward joules/sec and the reflected joules/sec.

> cause anything to happen.

May I direct you to page 388 of "Optics" by Hecht
where he asserts that total destructive interference
must be matched by an equal magnitude of total
constructive interference. Since there are only two
possible directions in a transmission line, total
destructive interference in one direction must be
matched by an equal magnitude of total constructive
interference in the opposite direction. From my
energy analysis article, a reference:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not
actually annihilated, ... All of the photon energy present in
these waves must somehow be recovered or redistributed in a
new direction, according to the law of energy conservation ...
Instead, upon meeting, the photons are redistributed to regions
that permit constructive interference, ..."

This is a very tough question: In a transmission line with only
two directions reckon what "redistributed in a new direction"
would necessarily mean? :-)

From his writings in "Reflections" and his postings
here, Walt obviously understands destructive and
constructive interference and the fact that (from
the Florida State University site):

"... All of the photon energy present in
these (cancelled) waves must somehow be recovered or
redistributed in a new direction, according to the
law of energy conservation ..."

In a transmission line we have two directions.
1. Toward the load
2. Toward the source

When the "photon energy" is "redistributed in a new
direction" in a transmission line, I'll bet it
goes in exactly the direction that Walt says it
goes.

Cecil,

If you go beyond your (unqualified) average view of the world and drilled down on the fields in the line as a function of time and position, and their relationship with steady state real and reactive energy flow at each end of the line in the general case, it may provide you with a more correct view of the tranmission line and its load and source in your favoured energy context.

I have done that, Owen, and let's see if your experience is
different from mine. Please go to the following Florida State
University web page:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

Leave the wavelength and amplitude the same. Change Wave A
to zero phase and change Wave B to a phase of 180 degrees.
The resultant superposed sum is zero obviously containing
zero energy.

What happened to the energy in Wave A and Wave B is
explained in the last paragraph. If Wave A and Wave B
occur in a transmission line, guess what happens to the
direction of the energy that cannot be destroyed?

Hi Cecil -

We've been over this a hundred times already. The only way to get
past it is for you to try to understand that my comment and Eugene
Hecht's are both true. You need to find a way to understand that
there is no contradiction. You could start by noting that Hecht does
not contradict anything that I said. Nowhere does he claim that
interference redirects energy. That's your claim! And I haven't said
that energy isn't redirected. If redirection of energy takes place,
it takes place by reflection - not interference. It's just basic optics.

> does not hold.

I have pointed out your errors and misconceptions
3-4 times and you have refused to correct them.
This is the last time I am going to waste my
time.

The source is a 2A Norton with a shunt 450 ohm
resistor. During steady-state, the source sees
75 ohms. Adding 1WL of 75 ohm lossless line doesn't
change anything but for the Nth time, points out
your errors and misconceptions.

source--1WL 75 ohm line--+--1000' 450 ohm line--75 ohm load
Pfor1--> Pfor2--> Pload
<--Pref1 <--Pref2

Taking your numbers, Pload = 220.4w, Pfor2 = 450w, and
Pref2 = 229.6w

Obviously Pfor1 = Pload = 220.4w and Pref1 = ZERO

The joules/sec into the impedance discontinuity must equal
the joules/sec out of the impedance discontinuity. Let's
see if they do.
Pfor1 + Pref2 = Pref1 + Pfor2
220.4 + 229.6 = ZERO + 450
450 joules/sec = 450 joules/sec

There you have it. You simply made a mistake. There is NO
violation of the conservation of energy principle. The
same conditions that exist at the impedance discontinuity
also exist at the source. Total destructive interference
toward the source is accompanied by total constructive
interference toward the load. Every sliver of energy is
accounted for. You analysis is, once again, simply wrong.

Please access the Florida State web page and set Wave A
to zero phase while setting Wave B to 180 degrees. Wave A
and Wave B continue to exist until they encounter each
other at which point their superposed amplitude goes to
zero indicating the the waves have been canceled. Since
energy cannot be canceled, where did the energy components
in the two waves go? Where it goes is explained at the
bottom of the web page. It is "redistributed", a synonym
for "redirected". In a transmission line, when the energy
is redistributed away from one direction, what other
direction can that redistribution take?

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

There is clearly total destructive interference between
Wave A and Wave B when they are of equal magnitudes and
opposite phases and energy redistribution necessarily
takes place.

In the past, you have said that redistribution of energy
from canceled waves is absolutely NOT a reflection yet
above you seem to say the redirection is a reflection.
Are you changing your mind about wave cancellation
resulting in reflections?

Thank you for your patience. With just a bit more we
might actually get some where.

> The source is a 2A Norton with a shunt 450 ohm
> resistor. During steady-state, the source sees
> 75 ohms.

Both true.

> Adding 1WL of 75 ohm lossless line doesn't
> change anything

Unfortunately, far from true. Much changes. Of particular
interest here is that there are now ghosts in the
transmitted signal indicating the presence of re-reflected
reflected signals. These were not present in the original
experiment.

> There you have it. You simply made a mistake.

I will not deny the possibility of mistakes. While proof
reading my example I found too many trivial arithmetic
errors to have complete confidence that none remain.
Still, you need to find the errors in my example, not
make changes to the example and then state there are
errors because the new example yields different results.

On the whole, I think progress is being made, though
painfully slowly. We have learned that adding a
wavelength of line does change things and this goes
against often quickly given conventional wisdom.

While the resulting steady state may be the same, the
transient response can be quite different. And, of
course, it is the transient behaviour that produces

ghosts.

To fully understand transmission lines, a student in the field needs to spend some time thinking about and understanding them in the time domain. Only by doing this will a complete understanding of the behaviour be possible.

In any case, we are back to the previous experiment for which no one has yet found any errors in the analysis. Until someone does, "Cecil's Hypothesis" does not hold.

Yes, they were. That is your point of confusion. You
cannot just willy-nilly declare that the reflections
have disappeared in violation of the conservation
of energy principle. The two configurations are
identical except for the additional delays which
don't change anything during steady-state. The ghosts
are still there as they always were. Your alleged
absence of ghosts never existed and is a dream which
requires violation of the conservation of energy
principle. You are free to dream but please don't
present your dreams as scientific reality.

> We have learned that adding a
> wavelength of line does change things ...

No, we have NOT learned that. We have learned that
adding a wavelength of line does NOT change anything
during steady-state and shines the light your previous
errors and misconceptions. The conditions at the source
are exactly the same during steady-state with and without
the 1WL additional line. Anything else would violate
the principles of distributed network theory.

> While the resulting steady state may be the same, the
> transient response can be quite different.

Yes, the transient response is somewhat different
because of the extra 1WL delay, but the steady-
state conditions are identical.

> In any case, we are back to the previous experiment for
> which no one has yet found any errors in the analysis.

I have pointed out your errors 5 times now. You can
lead a horse to water ...

Ramo and Whinnery give strict warnings about assumptions
of conditions inside a Norton equivalent source. You
didn't heed their warnings and got caught by your
misconceptions.

Hi Dennis,

I also have the RSC-8 (wire controlled version). I just put solder
bridges across the foil in the proper places. (They have a diagram?)
Of course by the time I got around to adding the "normally shorted" I
had long since lost the paperwork that came with it.

There has been so much corona around the top of that tower, I need to
replace the switch after about 4 years. The coax connectors are so
heavily etched they won't come apart. Inside the box is still nice and
shiny. No, I don't run that much power, but the tower has taken at
least 3 direct lightning strikes a year since it went up. Those are
just the ones the neighbors have seen, so it's likely more.

Can you demonstrate that without changing the configuration of
the experiment? Only then will your demonstration be convincing.

And just for greater certainty, I forgot to mention that the
reflection coefficient from the line to the generator is 0 in
my experiment (generator impedance is equal to the line
characteristic impedance) so using the reflection coefficient,
there are no reflections.

> > We have learned that adding a

True. But ghosts are a transient phenomenom, not a steady
state one, so things have changed, as I said.

So as I said, things are not the same. And ghosts are a transient phenomenom.

Please find errors without changing the experiment.

May I suggest again that obtaining a different result with a different experiment is not a surprise. If there are errors in my example, you need to find them there, not in some alternative experiment.

> Ramo and Whinnery give strict warnings about assumptions
> of conditions inside a Norton equivalent source. You
> didn't heed their warnings and got caught by your
> misconceptions.

You have misunderstood my generator. It is not a Norton equivalent, so any warnings from Ramo and Whinnery do not apply. Rather, it IS a generator with a current source and a parallel resistor. That is the experiment. So the computations of dissipations are valid for the experiment.

The issue I see is that they seem to use small established companies to do
some of their engineering for them- and then copying the product.
RigRunner, Rigblaster and now the W2IHY (?) equalizer come to mind. I am

sure there are others.

Anyone can demonstrate that by setting it up on the bench.
Guaranteed, you would see ghosting where you deny they exist.

> And just for greater certainty, I forgot to mention that the
> reflection coefficient from the line to the generator is 0 in

Because it is an active source, not a passive resistor,
your reflection coefficient is wrong.

> So as I said, things are not the same. And ghosts are a
> transient phenomenom.

OTOH, because of noise, steady-state cannot exist
in reality so fixed ghosting is as close to steady-
state as we are going to get.

> Please find errors without changing the experiment.

I did. Your simple-minded reflection coefficient is bogus.

> May I suggest again that obtaining a different result with a
> different experiment is not a surprise.

The two experiments are only different in your mind, not
in reality. The results of both experiments are the same
and you can prove it to yourself on the bench.

a new neighbor moved in today and deposited his LPDA TV antenna in the trash. It is one of the big ones, about 12 ft long elements tilted toward the front with a preamp box, No UHF yagi or corner reflector on the front. I have heard these are good on the UHF/VHF ham bands, any info would be appreciated.

From: Dennis Klipa <klipadk@gmail.com>
Message-ID: <1175137142.313281.27000@e65g2000hsc.googlegroups.com>
Source record: 44031

While searching for information on a 10 meter beam on this group, I got a reference to Manualmall at www.manualmall.com. I went to the site, found the manual and ordered it with my credit card. After submitting the data, I got a web page that said, "web page not found". When I tried to call the number on the web site, I got a phone company message that said, "If you want to make a call, hang up and dial the number." When I tracked down the person at the address listed at the web site, he told me that he had sold the business 2 years ago to some folks in Houston. I sent an email to the address listed on the site, but have not gotten a response.

Does anyone know if this business is still active or not? Has anyone ordered and received a manual from them in the last few months? Or do you know how to contact them? This is beginning to sounds real fishy to me.

Thanks,
Dennis

Referred to as Faraday Rotation.. ARRL handbook talks about it in the EME section. Rotation is less as frequency increases (so VHF is affected a lot more than UHF is affected more than microwaves)
Amount of rotation is determined by the total electron content in the path, which, of course, varies with everything you can imagine, but primarily the amount of sunlight.
It's related to the difference (dispersion) in propagation speed with frequency (or, index of refraction, if you want to work it that way)..

More than 360 degrees of rotation isn't unusual at VHF.

What's really interesting is that it rotates the same way no matter which direction you go, so if you had a planar reflector above the ionosphere, and you launched a wave that's say polarized North-South, and there's 45 degrees of rotation, when it came back down it would be rotated 90 and be polarized East West...

This is one reason why GPS radiates on more than one frequency (you measure the phase difference between the two, and that allows you to estimate the TEC, which in turn allows you to estimate the change in propagation velocity, which improves the accuracy of your fix.)

Most high accuracy orbiting radars that operate in P or L band do something similar, especially if they are making polarimetric measurements (handy if you want to do things like distinguish between trees and grass, for instance)

How much detail do you need? I can probably give you URLs to cover everything from simple estimates of magnitude to mind bendingly detailed theoretical discussions.

How much of it was new to the book?

Becasue he had a long series in CQ in the sixties on the topic, and I've
always assumed the book was merely a collection of the series, or at most
a collection of the series with some added material.

If that's the case, there's always the original series. IS CQ available
on CDROM these days, and at a reasonable cost? If so, that might be
an option.

Generally these cover two frequency ranges, 54 - 88 MHz and
172 - 216 MHz, These are Channels 2 -6 and 7 - 13, respectively.
Alternatively, your "find" might cover 54 - 108 and 172 - 216,
thereby adding the FM band.

I would not count on getting a good match on any ham bands,
except perhaps 6m. These are 300 ohm nominal impedance,
so you'd need to feed it with 75 ohm cable and a 4:1 balun or
find/make a 6:1 balun to use 50- ohm cable.

All is not lost. Remember that the analog TV cutoff is only
22 months away and you might just want a good VHF antenna
for digital. I'm getting digital TV over the air now and it's wonderful.

RELATED: The elements off an old TV antenna often make
suitable elements for home-brew antennas for 2m & 440.
The quality of the result depends on the extent to which you
can remount them skillfully on a new boom after you cut them
to size. My usual technique -- masking tape -- has yet to win
me any major awards!

Hi Jim

I am considering the design of a horn to illuminate an 8 foot diameter solid surface dish at 4 GHz, for reception of geosynchronous satellite signals that are linearly polarized.

One rraa reader has informed me that the rotation is refered to as Faraday rotation and gave some links to it. I see that the amount of rotation may be small enough to be negligable for my application.

I would like to know how rapid the rotation changes with time.

Thanks
Jerry

Cecil, I am talking about the way in the steady state in which energy is stored in E and H fields within the transmission line when standing waves exist, and the way in which energy is exchanged between E and H fields within the line, and the load and the source at each end of the line, and the net energy flow averaged over time (power).

Your analysis of energy waves or power waves doesn't give you the information to see that level of detail.

That depends on geomagnetic activity, because Faraday rotation is also a function of the earth's magnetic field.

With a signal that started out linearly polarized, there are three sources of change:

1. Simple geometry - if a geostationary satellite orbiting above the 0deg meridian has an antenna that is horizontally polarized when viewed from a ground location on the same meridian, that same antenna will appear vertically polarized when viewed from a location 90deg west. This effect is easily calculated and compensated.

2. Faraday rotation, as above.

3. Dispersion ("smearing") of the linear polarization, at times of high geomagnetic activity. From experience with a 432MHz array that had fully rotatable polarization, polarization could range from accurately linear at geomagnetically quiet times (with a very deep null at 90deg offset), all the way to dispersion of the signal around the whole 360 degrees. A completely dispersed signal will have a 3dB loss compared with accurately aligned linear polarization, so you have to include that possibility in your path loss budget. (At lower frequencies, dispersion is also accompanied by ionospheric absorption, but at 4GHz you may not need to worry about that.)

Bottom line: if you have enough signal/noise ratio to handle a permanent 3dB loss, then it will be much more convenient to ignore the fact that the signal started out linearly polarized. Instead, use a circularly-polarized feedhorn which will be insensitive to the polarization of the arriving signal.

Jerry, I am a little surprised that a geostationary satellite would use linear polarisation on a 4GHz feed, but that might just express a lack of experience.

A long time ago, I worked with the Intelsat series, and they were circular polarisation. Earth stations had no means of adjusting the orientation of feeds, they were RH or LH circular, the uplink was opposite to the downlink IIRC.

More recently, I worked on the design of a bird that used polarisation diversity. It used LH and RH circular, and reused the same frequency band on both polarisations.

If your bird is truly linear, you could use a circular antenna with a slight reduction in G/T, but with the flexibility of eliminating the orientation variable and the mechanical aspects of an antenna with adjustable orientation (remembering that the feed orientation will vary with position of the earth station).

Notwithstanding that transmission might be circular, the received signal might not be perfectly circular as a result of some of the effects you have described.

Sorry. No ghosts in my example.

For practical examples, you could consider any reference that
discusses driving digital signals down a transmission line.
One of the options for preventing reflections (which can
really mess up the reception of the signal), is matching
at the source. Others include matching at the load end.
The pros and cons of the various options will be discussed.

> > Please find errors without changing the experiment.
>
> I did. Your simple-minded reflection coefficient is bogus.

Reflection coefficient is actually quite simple.

RC = (Z2-Z1)/(Z2+Z1)

I challenge you to find any reference with a different definition.

But to explore your contention that RC is different when there is an active source, could you kindly provide the expression describing RC in such a situation.

It occurs to me that you may not be aware how to compute the impedance of circuit with active sources. Its quite simple. Replace the voltage sources with shorts and the current sources with opens. Then using the rules for parallel and series impedances, compute the result. Use this in the expression for RC.

> > May I suggest again that obtaining a different result with a
> > different experiment is not a surprise.
>
> The two experiments are only different in your mind, not
> in reality. The results of both experiments are the same
> and you can prove it to yourself on the bench.

Well, then just use my experiment so that we do not have to argue about whether they are the same.

When you compute the quantity of the re-reflection that my experiment generates, I will be convinced. But do not be surprised that I am not convinced when you compute the reflections for a different experiment.

Good day Dan,

I offer you the same challenge as Cecil, find the error in my
analysis and then compute the correct amount of re-reflection.

And provide the expression for computing RC in the presence of
sources if it is different than the conventional
RC=(Z2-Z1)/(Z2+Z1).

When you find nothing wrong with the analysis, ask yourself why
you don't believe the results?

Owen Duffy wrote:
> Your analysis of energy waves or power waves doesn't give you the
> information to see that level of detail.

Whatever level of detail one chooses, the energy
in the forward waves plus the energy in the reflected
waves will equal the total energy in the transmission
line which will always be the energy sourced and not
delivered to the load (in a lossless system). This
will be true right down to the last photon.

Unless someone can prove that EM energy is
transformed into some other form of energy for
storage in the transmission line and then transformed
back to EM energy when the transmission line is
emptied, the nature of EM energy and the conservation
of energy principle dictate what happens. EM (photonic)
wave energy cannot move at less than the speed of
light (modified by VF).

> Good day Dan,
>
> I offer you the same challenge as Cecil, find the error in my
> analysis and then compute the correct amount of re-reflection.

Since it can be quite difficult to locate errors in analysises,
I'll offer a simpler challenge to you and Cecil.

For the example I proposed, using the approach of your choice,
compute the magnitude of the first re-reflected signal to reach
the load.

Recall the line is 31 wavelengths long so the signal reaches
the load 31 cycles after the generator is turned on. There is
a reflection which reaches the generator 31 cycles later and
any re-reflection will reach the load after a further 31 cycles.

So you need to compute the magnitude of the reflection which
reaches the load after 93 cycles. This would be the first ghost.

You need to show your work. Handwaving -25dB will not be considered
as answering the question.

...Keith

PS. If you prefer, you may use a slightly different example for
which computation may be easier:
- the line is 1 second long
- the generator creates a 450 V step function at time 0
What is the magnitude of the re-reflection that reaches the load
after 3 seconds?

PPS. The answer to the two problems will be the same.

The flaws have been pointed out and you have ignored them.
THE REFLECTED WAVE DOES NOT SEE Rs=450 OHMS IF THE SOURCE
IS TURNED ON. THE REFLECTED WAVE DOES NOT EXIST IF THE
SOURCE IS TURNED OFF. Take a look at:

http://www.w2du.com/r3ch19a.pdf

> Sorry. No ghosts in my example.

Correction: No ghosts in your wet dream. I suggest that you
patent your ten cent solution to eliminate reflections and
sell the patent to Tektronix since you have obviously rendered
all those expensive circulators in the world obsolete. And why
would anyone go to the trouble of installing a 20 dB pad when,
according to you, a single ten cent resistor will perform better?

> Reflection coefficient is actually quite simple.
> RC = (Z2-Z1)/(Z2+Z1)
> I challenge you to find any reference with a different definition.

Sorry, all my references are at my new QTH but here are
a few from memory:

rho = SQRT(Pref/Pfor) = Vref/Vfor = Iref/Ifor = (SWR-1)/(SWR+1)

> One of the options for preventing reflections (which can
> really mess up the reception of the signal), is matching
> at the source.

Yes of course, one can do that with a circulator or pad. One
cannot accomplish "matching at the source" with a ten cent
resistor. Such an assertion is sophomoric.

We will be glad to do that if you will provide the
impedance value encountered by the reflected wave
with the source turned on. You have not yet done that.
Hint: It doesn't matter what impedance the reflected
wave encounters with the source turned off since
reflected waves are non-existent during that
condition.

Hi:
We just had a member that works in the satellite uplink/downlink business
at Penn State University give a talk on the subject. The satellites use
polarization as part of the frequency sharing system in geostationary
satellites. When they buy time on a satellite they are given a frequency
and a polarization to use. As there is a limited band of frequencies they
use polarization to help share frequencies with some working horizontal
and some vertical. The feeds on the dishes they use for uplinks and
downlinks have motorized polarization feeds and they adjust them to the
requested polarization.

The problem is completely solvable with the information
provided.

For examples of the methodology, google
'"lattice diagram" reflection'.

If your alternate methodologies require more information
to solve the problem, then I suggest that such alternate
methodologies are inferior to the standard one.

And to answer your question: 450 Ohms.
And to be more precise, the reflected wave continues for 62
cycles after the current source is turned off.

But truly, do look up lattice diagrams and learn the technique.
The number of problems that you will be able to solve will go
up significantly.

I would hope that the patent application would be rejected
due to prior art, but given the current state of the patent
office, I am not sure how much confidence I would have.

I expect that Tek is well aware and that were you to examine
the output circuits of their signal generators, there is a
very high probability that you will be able to locate the
voltage source and the 50 Ohm resistor. I know I just found
them on a randomly selected Agilent signal generator.

Yes, but these are less than useful aren't they. SQRT is
multi-valued so is never any use, and they all express
rho in terms of that which we want to derive rather than
in terms of that which we know. Means we need to know the
answer before we can compute the answer. Ooooopppps.

Hi Cecil -

Please, I've asked you this many times, quote me directly when you want to refer to something I've said. I am able to explain those things. I concede that I am unable to explain the convoluted ideas that you often attribute to me - although I do think I know why you write them the way you do. For the sake of clarity and simplicity could we instead try to restrict our dialog to the present discussion, and include relevant text that is quoted from the post we wish to comment upon? I think that's how it's customarily done in the newsgroups.

Nothing from the University of Florida contradicts what I said, and I can find nothing there to object to. My comments were directed strictly toward some of the things that you wrote. (As a courtesy I included the text I was referring to). I would like to suggest that you take more careful note of those areas where your words differ from those contained in the papers that you cite; in particular, with regard to interference as a *cause* for the redirection of energy. Do not infer, as you then risk inferring incorrectly. If you're honest about it, you will find that interference is the manifestation of a redirection of energy. It is the form; the envelope of the distribution. It is a result; the result of the superposition of waves. Nowhere in the literature will you find anyone describing interference as a cause of reflection, as you have done. That is because it is not a factual accounting of the natural phenomena.

Thanks and 73,

Jim AC6XG

Since your use of it yielded erroneous results, I think
I will pass. However, it appears to be much like the
S-Parameter analysis which does yield correct results.

An S-Parameter analysis indicates that you have made an
error in the reflection coefficient, s11, looking into
the 450 ohm transmission line. From HP's Ap-Note 95-1,
s11 is defined as the "Input reflection coefficient
with the output port TERMINATED BY A MATCHED LOAD."

You calculated your reflection coefficient with the
output port terminated by a mismatched load. There's
your conceptual error! The reflection coefficient, s11,
at the source is *NOT* the same as the reflection
coefficient at the load.

Have you told anyone else that an emitter follower with
a 450 ohm resistor in the emitter circuit will eliminate
reflections on all 450 ohm transmission lines?

If your "lattice diagram" really tells you to use a
physical reflection coefficient looking one way and
a virtual reflection coefficient looking the other
way within the same analysis as you have done, it
is worthless.

Here we are arguing semantics, not principles, again.
The total destructive interference that occurs during
wave cancellation leaves the associated energy with
no option except to be redistributed to an area of
constructive interference. Hecht says as much in
"Optics".

From "Reflections", by Walter Maxwell, 1st edition
Sec 4.3:

"The destructive interference causes mutual cancellation
of two complementary reflected waves ... Wave interference
between these two complementary waves ... causes a
cancellation of energy flow in the direction toward the
generator."

In the context that I am using the words, either
"superposition" or "interference" could be used. They
are two sides of the same coin.

Message-ID: <fh6o03l3gbkdsejfcs76v1aqq3h95ueldb@4ax.com>
Source record: 44069

The MFJ-998 IntelliTunerï¿½ has been advertised on the cover of MFJ's 2007 Catalog since late 2006. Orders have been placed at several major equipment vendors/dealers for several months. Production was promised in March 2007! But that date has not been met. I am sure that there are many folks out there that would like to know the latest information of this new product. Many are waiting to hear how it works and when they can add it to their systems. Feedback is requested.

3254. VSWR doesn't matter? But how about "mismatch loss"?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-29 20:10:46 UTC
From: billcalley <billcalley@yahoo.com>
Message-ID: <1175199045.962572.290380@e65g2000hsc.googlegroups.com>

What I gleaned from the excellent answers for the original "VSWR Doesn't Matter?" thread is that high VSWR doesn't really matter in a lossless transmission line environment between a transmitter's antenna tuner and the antenna, since any reflected RF energy will simply continue to "bounce" back and forth between the tuner's output impedance and the antenna's input impedance until it is, finally, completely radiated from the antenna without loss.

But then why does the concept of "mismatch loss" exist in reference to antennas? I have quickly calculated that if a transmitter outputs 100 watts, and the TX antenna has an impedance that will cause a VSWR of 10:1 -- using lossless transmission line -- that the mismatch loss in this "lossless" system would be 4.81dB! (Reflected power 66.9 watts, RL -1.74).

Since mismatch loss is the "amount of power lost due to reflection", and is as if an "attenuator with a value of the mismatch loss where placed in series with the transmission line", then I would think that VSWR would *definitely* matter, and not just for highly lossy lines either. But here again, I'm probably not seeing the entire picture here. What am I missing??

Confused!

If the system is Z0-matched, e.g. antenna tuner, there is
a mismatch gain at the tuner that offsets the mismatch
loss at the load so, in a lossless system, nothing is
lost. Wave cancellation toward the source is balanced
by constructive interference toward the load.

Yes John, I talked about that and I incorrectly used the term
"diversity", but it is frequency reuse as I noted using polarisation.

This can be done with circular (LH and RH) polarisation without a need to
rotate the feed unit, which for many installations will mean another
rotary waveguide joint which is to be avoided.

Launching circular polarisation in a feed horn is not difficult, and
developing autotrack error signals is relatively easy. An interesting
feed for amateur applications is the septum feed which gives access to
both circular polarisations from a fairly simple feed unit.

Sorry Jim, but I take exception to your statement, "If redirection of energy takes place, it takes place by reflection - not interference."

It is the interference between the forward and reflected voltages and beween the forward and reflected
currents that yields the resultant voltage and current values of rho at the matching point which produces
either a virtual short or a virtual open circuit that causes the re-reflection. I have shown this to be true
in my QEX article of Mar/Apr 1998, entitled, "Examining the Mechanics of Wave Interference in Impedance
Matching. It is also Chapter 23 in Reflections 2.

Using the complex values of rho I have shown the magnitude and phase relationships of the aforementioned
voltages and currents at the stub point that result in a virtual open circuit at the stub point to waves
reflected from a 3:1 mismatched load. The result is no reflections on the line between the stub and the
source, but a 3:1 SWR on the line between the mismatched load and the stub. If you don't have a copy of this
article please let me know and I'll send you one via email.

Real-world antenna tuners do have a loss but we previously
specified a lossless system. Of course, real world tuners
and transmission lines suffer losses but we all just live
with those losses while striving to minimize them. The point
is that an antenna tuner reflects most of the reflected
energy back toward the load thus accomplishing a mismatch
gain that offsets some, if not most, of the mismatch loss.
High SWR transmission lines are indeed lossier than flat
matched transmission lines of the same material.

That's basically true but ignores the stress that can be placed on the output circuit of the transmitter. Why do you think VSWR shut-down circuits are so popular? One can see rather high voltages or currents that are potentially damaging to the transistors and capacitors.

Now, since "lossless" is an abstraction and all materials have voltage and current limits, just make this easy on yourself and always strive for a VSWR of 2:1 or less. It simply works better and is more reliable.

But renders many all-HF-band dipoles useless. :-) I regularly
run up to an 18:1 SWR on my 450 ohm ladder-line. Owen's
transmission line calculator says I'm losing about 0.8 dB
in 100' of line under those conditions on 40m. IMO, it's
a small price to pay for all-HF-band operation.

I am not sure where you are going with this. As you map
the system for s parameter evaluation, which is the two
port network that you are evaluating? The generator?
The load? The line?

> Have you told anyone else that an emitter follower with
> a 450 ohm resistor in the emitter circuit will eliminate

That is a leap that I wouldn't make. An ideal source, as
used in this example, must be able to both source and sink
current. You will need to specify more for us to determine

whether the circuit you propose will achieve that to a
sufficient degree.

How many Ham transmitters have a balanced output?

How are you feeding a balanced line?

If you are using an antenna tuner with unbalanced in (50 ohms) and balanced
out (variable impedance), you should be OK in most situations.

Walt,

I am talking about the steady state.

I see discussion about this need for total re-reflection at the source, and some even describing the function of an ATU as a "total re-reflector", and it makes me wonder why we are grappling with re-reflection at the source end of the line in the steady state.

My understanding is that:
1. The ratio of elecric field to magnetic field per unit length (or V/I) in an infinite transmission line is constrained by the geometry of the line and the permeability and permittivity of the components carrying the two fields. That ratio is expressed as Zo.
2. If a wave with V/I=Zo reaches the end of the line, and the load does not permit V/I to be Zo (ie a mismatch), a reflected wave is launched, and it is of magnitude and phase such that (Vf+Vr)/If-Ir)=Zl (all complex values).

In the steady state, after all has settled (ie converged), the transmission line reaches an equilibrium where the source V/I characteristic is consistent with (Vf+Vr)/If-Ir) at the input end of the line.

Why is it necessary to complicate the analysis with tracking multiple re-reflections, potentially an infinite number of reflections of diminishing significance, an analysis that converges in the limit on the answer given by the solution of the source V/I characteristic and (Vf+Vr)/If-Ir) at the input end of the line (which is the equivalent input impedance). Note that (Vf+Vr)/If-Ir) at the input end of the line is determined solely by the tranmission line propagation constant, length, Zo and the far end load impedance, for avoidance of doubt, source impedance is not relevant.

Such an approach does not require invention of virtual re-reflectors or virtual s/c or o/c, or ATUs or pi couplers with virtual properties.

Owen

PS: Before someone brings up TV ghosts, they are not steady state phenomena. If significant distortion of modulation is caused by reflections, then clearly the scenario is not sufficiently steady state to allow steady state analysis.

If a tuner is placed directly after the TX and properly adjusted the TX
will always see a 50 ohm load and the shutdown circuit will always be
happpy. Again as long as the TX sees a match there is no unusual stress
placed on it. Remember that before the invention of coax cable SWR was
rarely considered. Instead the tx was tuned for proper established
operational parametrs and all was right with the world.

1:1 SWR CAN MEAN YOUR COAX IS FULL OF WATER.

Actually, as the one asserting it is possible, the
onus of proof is upon you to come up with a real-
world design (besides the one in your dreams). I
predict you will need something like a circulator
to actually dissipate the reflected energy. Your
violation of the conservation of energy principle
just won't fly.

No tuner! I don't like tuner losses. The feedpoint impedance
is always between 35 ohms and 85 ohms resistive. My choke
has an impedance in the thousands of ohms.

Your "amount of power lost due to reflection" statement would be true if
the line were connected to something resistive at the line's
characteristic impedance. With a properly tuned tuner, that's not the
case -- instead, the impedance looking into the tuner will also reflect
power, and in a way that makes it all work out so that the power all
ends up being radiated, which is what you wanted in the first place.

If you start considering loss in the tuner and the line then yes, a
greater mismatch between the antenna and the line will result in more
lost power (and more component heating in the tuner). You really want
to leave that subject be until you understand the properties of a
lossless system.

Well, there will be tuner losses, depending on how good the tuner's
components are.

> entire picture here. What am I missing??
>
> Confused!

Yes, you're confused.

If the lossless transmission line (obviously no such animal exists) were
tuned with a lossless tuner, then VSWR would not matter at all.

The loss due to mismatch in any real system will depend upon frequency,
VSWR, type of feedline, length of feedline, and the quality of the tuning
circuits used to match the system to the transmitter.

Let's take your example. 100 watt transmitter into, let's say 100ft. of
feedline at 10:1 VSWR and assume tuner losses are negligble (they often
aren't). Here are the losses for some different kinds of 50 ohm coax at
10mhz:

Belden 8237 2.19db
Belden 9913 1.63db

Belden 9258 3.19db
Belden 8240 3.71db
Belden 9201 3.83db

So, what's obvious here is that different coaxes have different losses at high SWR. Why is that? Because as power is reflected back and forth in a transmission line, the losses accumulate. So line that is very low-loss to begin with will be less affected by high SWR than line that has moderate to high losses when flat.

If 10 percent of the power in a line is lost travelling from the transmitter to the antenna, and if the antenna only radiates half that power, sending the rest back down the line, then 45 percent of the transmitter power is radiated immediately, while 45 percent is reflected. But only 40.5 percent reaches the tuner or transmitter. If ALL of that is re-reflected, then only 36.45 percent of the power is available at the second reflection to the antenna. The antenna will radiate 18.225 percent of the transmitter's power at this point, making the total 63.225 percent of the transmitter's output. Another 18.225 percent will be reflected again and, of that 16.4025 percent of the transmit power will live to be re-reflected from the tuner and 14.76225 percent will arrive at the antenna on the next bounce. Of that we can expect 7.381125 percent of the transmitter's total power to end up radiated while an equal amount starts its way back to the tuner. Anyway, it becomes a pretty simple bit of limit math to predict exactly how much will be radiated and how much lost in the coax under these conditions.

> relevant.

The answer is subtle. Consider the following lossless example.

XMTR--x--1WL 450 ohm line--y--1WL 450 ohm line--50 ohm load

The SWR is 9:1 everywhere on the 450 ohm line.
(Vf+Vr)/(If+Ir) = 50 ohms at points x and y. There are reflections
to the left of y but no reflections to the left of x. Why?

The answer is the interference
pattern set up by the 50 ohm environment left of x and the
450 ohm environment to the right of x. Total destructive
interference is occurring to the left of x and total constructive
interference is occurring to the right of x. That cannot be said
of point y yet the V/I ratio is identical to x. The physical rho
at point y is zero. The physical rho at point x is 0.8. That's
the difference. Reflections occur only at physical impedance
discontinuities.

In S-parameter terms at x: b1 = (s11)(a1) + (s12)(a2)

In RF terms at x: Vref1 = rho1(Vfor1) + tau2(Vref2)

The two terms to the right of the equals sign are the voltages
that engage in wave cancellation resulting in a Z0-match at x.

So to answer your question: The 50 ohm virtual impedance at point
y is incapable of causing reflections even though it has an identical
V/I ratio to point x. The physical impedance discontinuity at x is
fully capable of causing reflections along with the ensuing
interference.

Hi Bill,

As a short description, that is adequate.

> But then why does the concept of "mismatch loss" exist in
>reference to antennas?

"Mismatch loss" is a system description, not an antenna description.
So your reference is wrong.

>I have quickly calculated that if a

Two things wrong here:
1. You say nothing of a tuner inline;
B. Your math is wrong either way.

It does matter if you lack a tuner (in more ways that one). Most
discussion of "mismatch loss" omits such matters as tuners as it is a
separable issue. Combining these topics raises your chance of
confusion.

I think the confusion (which *always* seems to arise)
comes from the mix of the concept with the real world.
The concept claims that the system is lossless, so the
power bounces around until it eventually exits the "system"
via the antenna. Real world, the system is lossy, so
with all the bouncing around some of the power fails to
leave the system via RF radiation and instead leaves
the system via IR radiation. More heat, less RF.
Tastes great, less filling. :-)

Unless your coax decides that it had enough of all this current. I had
that happen once. The SWR had gone up and I pressed on. Then a muffled
boom outside and it became 100% reflective. Now I had to get on a ladder
and painstakingly scrape all the molten gunk off the stucco.

I find it strange that Hecht's definition of "interference"
doesn't even mention your alleged cause of the interference,
i.e. superposition. From "Optics", by Hecht in his own
bold italics:

"Optical interference corresponds to the interaction of
two or more light waves yielding a resultant irradiance
that deviates from the sum of the component irradiances."

One might argue that "the interaction of two or more light
waves" is superposition but why didn't Hecht choose
"superposition" instead of "interaction"? And a
"correspondence" of interference to the interaction of
the waves certainly doesn't imply cause and effect. It
seems instead to imply an inseparability between the
interference and the interaction of the waves which
is of course obvious.

Hecht seems to treat the superposition principle as more
of a set of rules to be followed by the interfering waves
than an actual act. FYI, the definition of "superpose"
doesn't mention EM waves at all.

It truly wouldn't matter if there were no such thing as resistance
and so on. The whole circuit could be tuned, with the transmission line
a part of it, and all of the power would go out the antenna.

Unfortunately, that's not the way reality works, more's the pity.

Every time those "standing waves" bounce back and forth, they warm
up the transmission line, the connectors, the transmitter tank, the
transmitter itself, etc, etc, and Entropy is conserved. ;-)

Hope This Helps!
Rich

Cecil, I don't understand what you mean by 'virtual impedance', why and how it differs from equivalent impedance (being the complex ratio of V/I at a point), and why it has these magical relection properties. Perhaps it is just an invention to support your proposition.

Given that my statement was qualified to the steady state, your inisistence that point x is different in behaviour to point y says to me you are silently changing scope to transient conditions to confuse the reader.

3284. MFJ-1795 HF Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2007-03-30 02:12:22 UTC
From: notme <nono@no.org>
Message-ID: <L76dnUm0c96Y75HbnZ2dnUVZ_u6rnZ2d@comcast.com>
Source record: 43950

Does anyone have any experience using the MFJ-1795 vertical antenna?
Because of it's size, it's probably one of the few antennas that I will be
able to put in my back yard.

I'd like to hear any comments on using this antenna, performance, etc...

Thanks!

The IEEE Dictionary seemingly goes out of its way to
try to emphasize the difference between a virtual
impedance and a physical impedor. Obviously, there is
a difference between a physical resistor and the ratio
of voltage to current called resistance where no physical
resistor exists. One is the (A) definition and the other
is the (B) definition. A virtual resistance does not
dissipate power. What? A dissipationless resistance?

If no physical impedance discontinuity exists, there can
be no reflections. V/I ratios, by themselves, with no
associated physical impedances, are a result, and not the
cause of anything. (The exception to that statement is a
source.)

The impedance looking into a transmission line is a virtual
impedance caused by system parameters. It is a result -
incapable of causing anything. Unless it is located at a
physical impedance discontinuity, absolutely nothing happens
because of the V/I ratio.

This is clearly not correct. Without the 75 Ohm line the first reflection does not arrive back at the generator for 62 cycles. With the 75 Ohm line, the first reflection arrives back at the generator after only two cycles. The response is not at all the same, though I agree, they do arrive at the same steady state condition.

The discontinuity between the 450 Ohm line and the 75 Ohm line produces a re-reflection back towards the load, which is one of the two sources of ghosts in your experiment, the other being the 75 Ohm line connection to the 450 Ohm generator. Remember that any impedance discontinuity produces a reflection. Without the 75 Ohm line, there are no reflections back towards the load and no ghosts (i.e. for the original experiment).

So the two experiments are clearly different. For the experiment without the 75 Ohm line (i.e. the original example), can you derive the magnitude of the re-reflected voltage that reaches the load and creates a ghost?

If so, please let us know the magnitude and how to derive it.

> Have you read w2du's web page yet?

Yes, but it is discussing, as its title clearly states, "Additional Experimental Evidence Proving Existence of Conjugate Match and Non-Dissipative Source Resistance In RF Power Amplifiers". I find it not applicable to the experiment at hand since we are neither discussing a reasonable implementation of an RF Power Amplifier nor is there a conjugate match.

Regardless, the real question is can you compute the magnitude of the re-reflection when it reaches the load and what is the methodology? (And please do not modify the experiment to do so.)

I am only talking about steady-state so the conditions are
indeed identical, as I stated.

> So the two experiments are clearly different.

No, technical theory says they have to be the same in the
steady-state condition. Saying they are different violates
the laws of physics.

That you find it "not applicable" is part of your problem.
You ignore reality in favor of your wet dreams. That's your
choice but please don't try to convince the rest of the
world to join you. The impedance seen by the reflections is
NOT the 450 ohm resistor. The impedance seen by the reflections
is the V/I ratio of the source.

> Regardless, the real question is can you compute the magnitude
> of the re-reflection when it reaches the load and what is the
> methodology? (And please do not modify the experiment to do so.)

I have asked you before - please provide me a math model of the
source and I will be more than glad to do so. Hint: Handwaving
the existence of a source is not acceptable. Where's the beef?

No, a properly calibrated Bird wattmeter will measure
some reflected power to the left of y but zero
reflected power to the left of x. Hint: Point x achieves
a Z0-match which re-reflects all reflected energy back
toward the load. That is a result of total destructive
interference toward the source and total constructive
interference toward the load, a concept that presently
seems to be beyond your comprehension.

> etc...

Firstly, I don't have first hand experience with the MFJ1795, however some thoughts...

It appears from their description and manual to be a vertical of 7 to 10 feet in height, and with top loading. They describe options for mounting on the ground, or an elevated mount with radials.

The challenge with any short ground mounted vertical is to increase the radiation resistance of the vertical and decrease the equivalent loss resistance of the ground connection.

Top loading helps increase radiation resistance, but the radiation resistance of a 10' radiator on 7MHz will be low relative to practical ground system resistances, and typical system efficiency with a minimal ground system is unlikely to be greater than about 25%. However, that might be a quite acceptable compromise to many users.

MFJ claims: 'The MFJ-1795 has a low angle of radiation for DXing and is omni-directional. The MFJ-1795 handles 1500 Watts PEP. It has highly efficient end-loading. The entire length of the antenna radiates and it has low SWR.'

Sounds impressive, but a low angle of radiation will require a superb ground system, it is likely to be omni-directional if there are no nearby obstructions, radials will distort the pattern if there a few in number, end loading might have some loss advantages, but ground resistance may swamp loading loss and largely determine the antenna efficiency. Improving the ground system may increase VSWR and increased line loss might eat away some of the gains.

Vertical antennas are often quite noisy relative to a horizontal antennas in built up areas, something to consider.

Owen

An understanding of "mismatch loss" doesn't require SWR, reflections, power waves, "reflected power", "reflected energy", or other real or imagined complexities other than simple impedances. Here's what it means:

If you have a generator with a fixed output impedance such as a signal generator, and connect it to a conjugately matched load, the power dissipated in that load is the most you can get in any load connected to the generator. For example, if your generator produces 10 volts RMS open circuit and has a 50 ohm resistive output impedance, it can deliver 0.5 watt to a 50 ohm resistive load. If you connect any other load impedance to the generator, you'll get less power to the load. You can calculate exactly how much with simple circuit theory.

"Mismatch loss" is simply a way of expressing the reduction in power you get due to the load being mismatched, compared to how much you'd get with a matched load. For example, if you connect a 100 ohm resistor to the output of the generator, it would dissipate 0.44 watt instead of 0.5, so the mismatch loss is 10 log 0.5/0.44 = 0.51 dB(*). If you connect a 25 ohm resistor to the output, you also get 0.44 watt in the load resistor, again a "mismatch loss" of 0.51 dB. These numbers are calculated using nothing more complicated than simple lumped circuit principles.

Mismatch loss is a useful concept when connecting fixed-impedance circuits together, such as in a laboratory environment. But it doesn't apply to either antennas or to VSWR. All you have to do to reduce the "mismatch loss" to zero is to insert a tuner or other matching network between the generator and the load. Presto, the generator sees 50 ohms resistive, the load dissipates 0.5 watt, and the mismatch loss is zero.

(*) For the 100 ohm example: The circuit consists of a 10 volt generator, and a 50 ohm resistance (the generator impedance) and 100 ohm resistance (the load) in series. So the current is V / R = 10 / (50 + 100) = 66.67 mA. The power dissipated in the load is I^2 * R = 0.06667^2 * 100 ~ 0.44 watt. No reflections, VSWR, transmission lines, or bouncing power waves required.

Deep in the manual, I find:
1. the expectation that VSWR on 40m is likely to be around 1.2, and
2. that the unloaded part of the radiator is adjustable from 5' to 8'.

Following from 2, modelling indicates that a top loaded 8' vertical
probably has a radiation resistance around 5 ohms on 7MHz.

From 1, assuming that VSWR 2 is at the feed point and is achieved with a
feed point resistance of 42 ohms, then efficiency at the feedpoint = 5/42
or 12%.

The VSWR is so good that line loss with 100' of RG8/X for example should
give an antenna system efficiency of around 10%.

There's also the case where a perfect VSWR does no good. That happens
when you connect a transmitter to an extremely lossy line and the
signal dissipates before it gets to the load :>

You clearly have never calibrated a Bird Wattmeter for a 450 Ohm Line
(or any line).

As for this "some" power. "Some" power can be "measured" by any of a
half dozen ways to improperly use instrumentation. It doesn't lift
the gravitas of a "hint" to proof.

That does cause some difficulties since we are discussing ghosts,
clearly a transient phenomenom. Remember the question: What is
the magnitude of the first re-reflection to reach the load?

> > So the two experiments are clearly different.

But what a surprise, that is 450 Ohms. Try plotting it. Compute
the slope.

> > Regardless, the real question is can you compute the magnitude

>
> I have asked you before - please provide me a math model of the
> source and I will be more than glad to do so. Hint: Handwaving
> the existence of a source is not acceptable. Where's the beef?

Sure, why not? Just for fun let's do the Norton model for the
generator. A 2 Amp ideal current source in parallel with a
450 Ohm resistor. Recall that an ideal current source has an
infinite impedance and adjusts its voltage to whatever is necessary
to cause 2 Amps to flow. This is quite a simple model and
EXACTLY models the generator because it is the same as the
definition of the generator used in the experiment. It is
quite amenable to analysis.

Remember that the question to be answered is: What is the
magnitude of the first re-reflection to reach the load?

Use the methodology of your choice, but you can't make any
changes to the circuit since such changes might alter the
transient behaviour. Hints:
- steady state analysis is unlikely to work since the
question is about the transient behaviour.
- for a methodology that works try googling lattice diagrams.
These are specifically applicable to the transient behaviour
of a system.

And to get any marks at all, show your work along with the answer.

Good luck.

Ok, I have seen that. It isn't that the antenna isn't tuned, it is
tuned with the twin-lead instead of a conventional tuner.

I might have enough twin lead to build one of those. I'll have to
consider it. It has always tweaked my interest.

Thanks

Certainly true. To be somewhat more complete there is another
rho at x. You have correctly computed rho from the generator
to the line, but there is also a rho from the line to the
generator: -0.8. This can handily be used to compute the
magnitude of the reflected signal that is re-reflected
towards the load. And when dealing with transients, will
permit you to compute the magnitude of the ghosts, of
which there are an infinite number for each change in
the signal, though of declining magnitude. In a sense,
the ghosts show how the system settles to its
'steady-state'.

It is 450 ohms under no load conditions. It drops when
one adds the load. Please read w2du's web page to find
out why the reflections do not see 450 ohms and so are
re-reflected.

Not exactly correct. Rho is calculated at a point
of discontinuity, not from-to along a line. The
reverse rho at point x is -0.8. There could
exist another point of discontinuity inside the
source but unless reflections are allowed to reach
the source, we have no clue what it might be. If
100 volts is supplied at point x in the example,
we have no way of knowing what the source impedance
might be.

I am curious to know, have you measured the power both at the antenna
and the radio to see what loss there might be? I wouldn't expect very
much, personally.

On a G5RV, it is taught that the twin-feedline is also part of the
antenna itself, is that true in your model as well?

thanks

http://www.w5dxp.com/notuner.htm

Cecil,

Looking more at your antenna, I am making several observations. I posted the URL at the top for other readers to know what we are talking about.

I kind of wish you would change the name of the antenna and not call it 'no-tuner' because I feel let down every time I look at it and see the feed-line tuner. I realize it isn't a conventional tuner. Don't get me wrong, I think it is a GREAT idea and I like it very much and would like to try it myself. However, I feel it is a little deceptive in the name.

I have a few questions about the system. I may have asked some already in another thread, so please bear with me. This is a better place to discuss it rather than hijacking another thread.

I see you use 450 ohm ladder line (or window-line as some call it.) I am wondering if the concept will also work with other impedance feedline such as 600, 300 or 75 ohm twin-line or even possibly with coax. ****

**** I just looked over your program. I see that you have it setup to allow 300 or 450 ohm ladder line. I wonder if you have LLWL available for 600 and 75 ohm.... I will try to put this in XL. (I don't have a basic program.) OK, I just found the compiled program.

I am interested in making one, but I only have 300 ohm.

Does the feedline act as part of the antenna? I am sure it will, at least up to the 'no-tuner' if it acts like a G5RV, but do you know if the feedline radiates?

Have you measured the power at both sides of the 'no-tuner' to see what loss there might be? I doubt there would be much considering that you are using window-line.

I see a couple of the frequencies are above 1.5:1, which I am not comfortable going over with solid state rigs. Do you think that could be fine-tuned with the addition of a 1/2 foot section or maybe with that and a 1/4 foot section?

Would it be safe to assume that I can create a mono-band dipole, maybe even multi-band - if I am lucky, by fixing the length of the dipole and the feedline such that the increment gives me the imax at the

balun for the desired frequency(s)?

Finally, you have a 1:1 choke at the feeder. I see that the better quality coax, the more toroids are needed. Would there be a problem with using a foot of RG-58 with the fewer toroids and then connect that to the high-quality line? I suspect that by then the common-mode currents will be gone and there would be minimum loss in such a short strand of lower-grade coax for HF. I doubt there would be a noticeable signal loss.

Does the 'no-tuner' feedline need to be spread out. I see from the photo that your 16 foot section is one large loop, I figure it must be close to a four-foot diameter loop.

Is there a similar system that would work with a vertical?

Thank you,

I appreciate your taking time to answer this. I hope many of us can learn from it.

>contradicted by physical laws?

Hi Jim,

It's been a long time since we discussed this point, so I've forgotten how we ended up on
it. The part I feel
is contradicted is that when total re-reflection is caused without a total discontinuity
such as a physical
short or open circuit, it is caused by resultant of the interference between the forward
and reflected
voltages and the interference between the forward and reflected currents. When the phase
relationships between
the respective voltages and currents are correctly adjusted to achieve an impedance match,
the resultant is
either a virtual short circuit or a virtual open circuit, which causes total re-reflection
of the waves
reflected from the mismatched load terminating the line. Consequently, the interferences
cause the
re-reflection.

Are you saying that this explanation of the re-reflection concept is incorrect?

Walt

Based on the fact that the antenna is being fed maximum current at the
center, I would guess that this should work.

Hi Owen:

In this case the feed point has for lack of the right name a "pick up
loop" that is motorized and that is what turns for the differnt
polarisation. It is linear, not circular polarisation, at least on the
geostationary satellites they use. I would guess that linear is easier
for them to change. The way it works is they call a satatellite broker
and buy time, he gives them a satellite, a frequency and a polarisation
to use. Before the requested time the satellite transmits a test signal.
They tune to that frequency and tune their antenna for max signal, then
they transmit a test signal to the satellite, the satellite operator
verfies that their signal meets spec.'s and then the channel is theirs

for how every long they have paid for. It's more of a hands on operation than I would have though. Their main busness is sports as they up load all the sports events here on campus and for many of the non sports events like news events and some classes that are held via satellite.

>I am talking about the steady state.

Hi Owen, so am I. The value of (Vf+Vr)/(If-Ir)= Zi is the result of the convergence of all reflected waves.

>I see discussion about this need for total re-reflection at the source,
>and some even describing the function of an ATU as a "total re-
>reflector", and it makes me wonder why we are grappling with re-
>reflection at the source end of the line in the steady state.

If we don't consider re-reflected waves at the source end of the line the source is never going to deliver all
of its available power.

>My understanding is that:
>1. The ratio of elecric field to magnetic field per unit length (or V/I)
>in an infinite transmission line is constrained by the geometry of the
>line and the permeability and permittivity of the components carrying the
>two fields. That ratio is expressed as Zo.
>2. If a wave with V/I=Zo reaches the end of the line, and the load does
>not permit V/I to be Zo (ie a mismatch), a reflected wave is launched,
>and it is of magnitude and phase such that (Vf+Vr)/If-Ir)=Zl (all complex
>values).

This is true.

>In the steady state, after all has settled (ie converged), the
>transmission line reaches an equilibrium where the source V/I
>characteristic is consistent with (Vf+Vr)/If-Ir) at the input end of the
>line.

Not yet. There is more to be done.

>Why is it necessary to complicate the analysis with tracking multiple re-
>reflections, potentially an infinite number of reflections of diminishing
>significance, an analysis that converges in the limit on the answer given
>by the solution of the source V/I characteristic and (Vf+Vr)/If-Ir) at
>the input end of the line (which is the equivalent input impedance). Note
>that (Vf+Vr)/If-Ir) at the input end of the line is determined solely by
>the tranmission line propagation constant, length, Zo and the far end
>load impedance, for avoidance of doubt, source impedance is not
>relevant.

Without inserting some sort of matching device between the source and the line input for causing re-reflection
of Vr and Ir, (Vf+Vr)/(If-Ir) will not equal source V/I, and consequently the source will not deliver all its
available power. When Vr and Ir are caused to be re-reflected in phase with Vf and If, respectively, the
source will deliver all its available power, because the line-input Z will now equal source Z = V/I.
Therefore, the source impedance is totally relevant.

The matching device that causes Vr and Ir to be re-reflected is either a virtual oc or a virtual sc, which is
produced by adjustment of the device that orients the appropriate relationship between the forward and
reflected voltages and between the forward and reflected currents.

>Such an approach does not require invention of virtual re-reflectors or
>virtual s/c or o/c, or ATUs or pi couplers with virtual properties.

Well Owen, then how do you explain re-reflection at the souce in the absence of z virtual sc or oc?

Walt

> coax. ****

Might as well go into some detail here. The feedpoint impedances
encountered in a 130 foot dipole may range from ~50 ohms to
~5000 ohms. In order to limit the maximum SWR the feedline Z0
should be ~SQRT(50)(5000) = ~500 ohms. Thus the choice of 450
ohm line. Given that the feedpoint impedances may range from
~50 to ~5000 ohms, here are the maximum SWRs that may be
expected for the different Z0s. Since the antenna system
is fed at a current maximum point, I have included the
impedance at the current maximum point which needs to be
between 25 ohms and 100 ohms in order to avoid foldback.

Z0 SWRmax Imax Impedance
600 12:1 50 ohms
450 11:1 41 ohms
300 17:1 18 ohms
75 67:1 1 ohm
50 100:1 0.5 ohms

It should be readily apparent why coax is a no-no for this
antenna system. Even 300 ohm twinlead will result in a
50 ohm SWR of 50/18 = 2.8:1, high enough to cause foldback.

> I am interested in making one, but I only have 300 ohm.

Let's take 40m as an example. The dipole is one wavelength
and will have a 300 ohm SWR of 16:1 on 7.2 MHz according
to EZNEC. 300/16 = 18.75 ohms at the current maximum
point resulting in a 50 ohm SWR of 2.7:1 enough to cause
foldback without an antenna tuner. Such is life.

I do use 300 ohm line on my 20m rotatable dipole and it
does work 20m-10m but there are probably 10m frequencies
where the 50 SWR is too high.

> Does the feedline act as part of the antenna? I am sure it will, at
> least up to the 'no-tuner' if it acts like a G5RV, but do you know if
> the feedline radiates?

I monitor the current balance in my feedlines. They are
so well balanced that there is no hint of common-mode

current on the coax side of my current/choke/balun.
Balanced currents radiate a negligible amount.

> Have you measured the power at both sides of the 'no-tuner' to see
> what loss there might be? I doubt there would be much considering
> that you are using window-line.

No I haven't measured the losses. I have trusted Owen's
transmission line calculator for that data.

> I see a couple of the frequencies are above 1.5:1, which I am not
> comfortable going over with solid state rigs. Do you think that could
> be fine-tuned with the addition of a 1/2 foot section or maybe with
> that and a 1/4 foot section?

The disadvantage of this method is that it lacks one dimension
of tuning necessary to achieve 50 ohms. Unless you do one more
impedance transformation, no amount of fine-tuning the ladder-
line length will get any closer.

> Would it be safe to assume that I can create a mono-band dipole, maybe

> and the feedline such that the increment gives me the imax at the
> balun for the desired frequency(s)?

One such example is at: http://www.w5dxp.com/HEDZ.htm
This antenna works on 75m and 40m with a fixed length of ladder-
line.

> Finally, you have a 1:1 choke at the feeder. I see that the better
> quality coax, the more toroids are needed. Would there be a problem
> with using a foot of RG-58 with the fewer toroids and then connect
> that to the high-quality line?

Just use RG-58 entirely unless you are running high power.

> Does the 'no-tuner' feedline need to be spread out. I see from the
> photo that your 16 foot section is one large loop, I figure it must be
> close to a four-foot diameter loop.

I have my 16 foot loop coiled in a 4 turn spiral around a piece
of fiberglas fishing pole.

> Is there a similar system that would work with a vertical?

Verticals are not usually fed with ladder-line so probably
more trouble than it is worth.

Walter Maxwell wrote:
> Well Owen, then how do you explain re-reflection at the souce in the absence of z virtual sc or oc?

I'm not Owen but in S-Parameter terms it is explained by:

b1 = (s11)(a1) + (s12)(a2) = 0

When (s11)(a1) equals -(s12)(a2), there is total destructive interference in the direction of b1 toward the source. That's the wave cancellation that is associated with your sc and oc. As the Florida State web page says:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are 180-degrees ... out of phase with each other meet, they are not actually annihilated, ... All of the photon energy present in these waves must somehow be recovered or redistributed in a new direction, according to the law of energy conservation ... Instead, upon meeting, the photons are redistributed to regions that permit constructive interference, so the effect should be considered as a redistribution of light waves and photon energy rather than the spontaneous construction or destruction of light."

In a transmission line with only two directions, a "redistribution" certainly implies a reversal in direction of the wave energy involved in the wave cancellation, i.e. a re-reflection.

On the above Florida State web page, one can set the two waves to the same frequency, same magnitude, and opposite phase and observe the wave cancellation. Question is: What happens to the energy in the canceled waves in a transmission line?
Answer: re-reflection in the opposite direction.

>it is caused by resultant of the interference between the forward and reflected
>voltages and the interference between the forward and reflected currents.

Here I read the causal connection between the subject and the
condition.

However, waves do not mix in a linear space. The proof is the lack of
heterodyning of the RF soup we live in. Further, interference is the
mixing product of at least two sources (waves, what-have-you) in a
load. No load, then no interference.

Unfortunately, to raise the prospects of interference requires that
load, and requiring that load immediately violates the first condition
above - no physical manifestation.

cause the
>re-reflection.

All of this is true in isolation, in fact it describes the actions of
a physical load called an ATR/TR Tube in a RADAR waveguide. When the
right wavelength conditions of a wave and environment meet in the
tube, formerly an open it now conducts to create:
1. A literal short;
2. A short that is found at even quarterwave intervals;
3. An open that is found at odd quarterwave intervals.
The physical and literal short was first necessary as the initiator.
Without the tube, the co-mixing of waves would not have done the job

in isolation.

Oh, 'cmon Richard, are you saying that if a load reflected wave incident on the source wave doesn't result in
an interference between the two waves? If this is what you're really saying, then it is equal to saying that
the principal thrust of my book Reflections is wrong. Is this what you mean? And are you saying that the
report of the Fl State professors that Cecil referred to is also wrong?

In addition, when the radiation from two dipoles fed from the same source is of the same magnitude and
opposite phase at a point in space, resulting in a null in the radiation pattern at that point, are you saying
that the radiation from the two dipoles is not in interference at that point? If this is what you're saying,
then how is the null in the pattern created?

Walt

Cecil,

You seem to misinterpret the significance of the "weasel words" used by your various author-gurus.

An expression such as, "Optical interference corresponds to the interaction . . .", without any accompanying equations is intended to give the reader a general feeling for what is going on. Such words do not imply cause and effect. Nor should those fuzzy expressions be taken to imply "inseparability" as a rigid requirement.

Interference is merely a convenient description of what happens when waves meet. There are no equations for "interference"; there are no units for "interference"; there are no standard symbols for "interference". Interference is an observation, not a physical law.

Stick to the standard field equations and you will not be misled. I am confident that somewhere Hecht goes though the standard treatment of

setting up field functions with boundary conditions and then solves the equations to show what happens at interfaces. Interference can be seen in the solutions to that problem. I'll bet he does not start with interference and then proceed to determine the E-fields and H-fields.

Superposition is a basic mathematical concept that applies to linear systems. It is not necessary to catalog every possible application for superposition. The fact that your definition of "superpose" does not mention EM waves is of zero importance in the world. Superposition still applies even if your dictionary does not know about it.

Gene Fuller wrote:
> There are no equations for "interference";

On the contrary, quoting from "Optics", by Hecht,
page 283, 4th edition: "It follows from Eq.(7.9)
that the resultant flux density is not simply the
sum of the component flux densities; there is an
additional contribution, 2*E01*E02*cos(A1-A2), known
as the *interference term*. The emphasis is Hecht's,
not mine.

Later on page 388: "The interference term becomes

I12 = 2*SQRT(I1*I2)cos(Gamma)"

What does it take to make that look like an equation
to you? Have you ever taken time to read and understand
"Optics", by Hecht?

I suspect you would consider blowing smoke through
a region of interference or any other means of detection
to be a "load"? (It is left to the readers to conclude
what it is a load of.)

So the real question is metaphysical: Does undetected
interference exist and if so, how does one prove it?
Reminds me of some of the steady-state arguments.

The students of Aristotle would argue that the interference
exists whether it is detected or not. (A thing is what it
is.)

The students of Plato would argue that the interference
doesn't exist unless it is detected. (A thing is not
necessarily what it appears to be.)

Dave, I'm pretty sure I know what you mean here, but it should
be noted that this isn't entirely true. The line would have to have a
couple
of other characteristics besides being simply "lossless" for VSWR
not to matter at all.

The problem, of course, is that a VSWR of other than 1:1 implies
(by definition!) that the voltages and currents along the length of
the line are not constant; there are cyclic variations in each, with
maxima and minima located at half-wavelength intervals (that's
the whole "standing wave" thing in the first place, right?).
Particularly in high-power situations, it is possible for the maxima
to exceed the ratings of the source or of the line itself.

Not at all; "entropy increases" is with respect to the total
entropy of a closed system. But in the case of "evolution,"
the only closed system which makes any sense to consider
is the entire solar system, or at the very least the Sun-Earth
system. It is entirely pemissible for an overall increase in entropy
to occur (i.e., the Sun slowly loses energy to the rest of the
universe) while at the same time this overall trend results in
a very localized DECREASE in entropy (increase in order;
in this case, the evolution of complex systems on Earth).

The folks on this newsgroup who argue that the concept
of reflected energy is invalid and only standing waves
exist seem forced to abandon the principle of
superposition which states that a system can be
analyzed by considering the components separately
and adding them later.

So does the Superposition Principle give us permission
to analyze the forward wave and the reflected wave
separately, or not?

An S-Parameter analysis obviously considers the
forward wave and reflected wave separately. Is such
an analysis invalid or simply honoring the rules set
forth in the Principle of Superposition?

>>>short or open circuit

What is in your "without a total discontinuity" that is now found in
your "load reflected wave?"

Are we to now parse "total discontinuity" as being wholly different
from "partial discontinuity" such that waves suddenly mix from that
difference?

My example of the classic AT/ATR tube evidences EVERY observation you
offer, except it is a necessary load without which those observations
would never appear. If I were to replace its "total discontinuity"
with a weak tube (it exhibits less than total short); it too would
exhibit EVERY observation you offer EXCEPT they would be imperfect or
"partial discontinuities" repeated every quarter wave. It is obvious
that the effect follows the physical load, not the waves (they haven't
changed when the tube went bad). The physical load is the principle
in the process of interference.

There is absolutely no example of interference that does not rely on a
load to reveal it.

I moved here about seven months ago. There is not HOA, but some neighbors are rather sensitive to how others keep their property in our modest street of 34 homes on lots about 70 x 120. I just upgraded to General. So far, I've got a 40m dipole that is just strung across the back of the roof, but I plan to string it between a tree and the chimney when I get a chance.

I would appreciate your ideas on how to calm down neighbors that might be worried about RF interference, appearance, and property value.

> the absence of z virtual sc or oc?

There is no need for complete re-reflection and therefore no need
to invent a virtual sc or oc.

It is easier to explain outside of a generator so let us consider
two transmission lines of different characteristic impedance
joined in the centre of our page. For convenience assume the
generator is on the left and the load is on the right.

Further, the forward voltage on the left line (Vlf) exists, while
the reverse voltage (Vlr) is zero.

On the right section of the line there is both a non-zero forward
voltage (Vrf) and reverse voltage (Vrr).

(The above could be physically achieved when the section of the line
on the right is being used as a quarter-wave matching transformer.)

Now how can it be that Vlr is 0 unless Vrr is completely
reflected?

Easy. Two things happen to the Vlf, part of it is reflected
and part of it goes through; the amounts controlled by RC.

Two things also happen to Vrr, part of it is reflected and
part of it goes through; the amounts controlled by -RC.

The conditions to satisfy that Vlr be 0 is simply that
the contribution to Vlr from the reflected Vlf is equal and
opposite in sign to the contribution from the part of Vrr
that goes through.

Doing a little algebra will reveal that when the above condition
is satisfied, Vrf is equal to Vlf minus Vrr, but this is purely
numerology and should not be take to mean that all of Vrr is

re-reflected. Once this is understood there is no need for complete re-reflection or virtual short or open circuits.

A little mental exercise will show that the conditions described above for the connection of two transmision lines is isomorphic to the conditions at the generator output terminals so the same explanation can be applied there.

Do they know you're a ham? If not, you could just say its an SWL
antenna. or you could use as small wire as possible to make it fairly
invisible. Not sure what you can do about the feedline, though, for
invisibility... or you could try to put the feedpoint somewhere near an
object that could hide or mask it. I situations like yours, some sort
of vertical might be better....

I wish you luck. I know there are many things I haven't thought of
that may work for you.

Well I guess that settles it. You clearly are not aware of the
methodologies. Even ones that work on the simplest of examples.

But this is positive. Once you know what you don't know, you
can move forward with education.

The question is answerable with the information provided. All
that is needed is to know the methodology.

I suggest again, google '"lattice diagrams" reflection'.

Alternatively, just ask and there are many here who would
be willing to assist you (or anyone else) with learning the
techniques.

Walt, it seems to me from your comments that fundamentally you disagree with the above statement.

Let me work a simple, but practical example. Apologies for the example being two cascaded transmission line sections to demonstrate that you do not need S parameters to solve the problem.

We have a G5RV with a feed point impedance (Z1) of say 90+j10 at 14.2MHz.

The feed point is connected to 9.85m of Wireman 554 ladder line. The propagation constant (gamma) for the line is 6.80e-4+j3.20e-1 and Zo is 360.00-j0.56. Using gamma, Zo and Z1, the input impedance to this section of line (Z2) is 92.37+j15.06. Due to line losses, only 97.2% of the input power passes into the load.

The ladder line is connected to 11m of Belden 8267 (RG213) to the transmitter. The propagation constant (gamma) for the line is 2.71e-3 +j4.51e-1 and Zo is 50.00-j0.27. Using gamma, Zo and Z2, the input impedance to this section of line (Z3) is 27.44+j4.18. This input impedance is not dependent on the transmitter, it does not matter whether the transmitter contains a pi coupler, an ATU, a broadband coupled output with or without low pass filters, or any kind of "total re-reflector" invention. Due to line losses, only 93.1% of the input power is passes into the second line section, and therefore only 93.1% of 97.2% or 90.5% of the input power passes into the load.

The amount of RF power from the transmitter will be the power that the transmitter delivers to a load of *any* kind of load of that same impedance (27.44+j4.18). If you adjust a valve transmitter's pi coupler to optimise power output into this load, you a merely adjusting the transformation of the external load to suit the valve's available voltage swing, current swing and conduction angle (within linearity, dissipation and drive constraints). The optimal values of the pi coupler components are readily calculated for the the valve's available voltage swing, current swing and conduction angle, and such is routinely done in engineering design of PAs.

There is no need to resort to the invention of a "total re-reflector" to describe how this works.

Owen

PS: the solution of the tranmission line segments using load impedance, characteristic impedance, and propagation constant uses the transmission line formula that can be found in any good transmission line text. The values given for gamma above are for length units of a metre.

I hope the maths was correct above, it is unchecked and I may have embedded some errors, but the method is correct, the line sections were solved using the calculator at http://www.vk1od.net/tl/tllc.php .

The only dispute about superposition that I have observed is
that it does not apply to the computation of power which can
easily be demonstrated by the most trivial of examples.

Superposition of voltages and currents seems to be quite
accepted and is an excellent tool for circuit and transmission
line analysis.

Cecil,

That quote agrees completely with what I said. Interference is a description of the equations. It is not a part of the equations per se. Do you see anything in the quoted equations that looks like a symbol for "interference"? I see E, A, I, and Gamma, but nothing that would seem to represent "interference". Is there a hidden variable in there somewhere?

You keep trying to make interference act as some sort of primary physical law rather than merely a convenient observation and description. No wonder these threads go on forever.

Nobody denies the existence of interference. However, interference is the result of all the equations and calculations, not the source.

Gene, IMHO the terms "constructive interference" and "destructive interference" are poor terms. If "interference" describes essentially the phasor result of summation of two (or more) phasor (ie coherent) quantities, then there is no need for the constructive and destructive qualifiers if the phase relationship is given (and it must be to perform the summation).

The two terms are often used to mean total reinforcement (0 deg phase difference) or total cancellation (180 deg phase difference and equal amplitude). I note the Wikipeadia page at http://en.wikipedia.org/wiki/Destructive_interference infers that usage.

To my mind, there is so much loose usage of the terms to consider that a reader will reliably understand what the writer meant, and so in the interest of better communication, I don't use them.

The in-phase and out-of phase, equal amplitude cases are a very small subset of the real world cases that are of interest in solving transmission line problems, yet they dominate, possibly cause, the simplistic discussions in this place.

The usage here appears to derive from a certain person's need to use terminolgy and examples from other electromagnetic radiation applications to describe transmission lines. So far, it seems that when the alternative explanation disagrees with the direct explanation, the flaw has been in adaptation of the alternative explanation to the problem.

A friggin' WIRE ??? Wow your neighbors are one step away from the funny farm, aren't they? Paranoia-ville, USA.
Ok, here's what you do, get a picure of a tower farm (check on the web, maybe W0AIH is a good place to start, or try any of the big dxers listings on QRZ.com). Then tell your neighbors (only if they ask, don't go looking for trouble!!) you are thinking of a nice 80 ft tower/beam, but if the dipole works ok you will probably just keep it. However, if there are any interference complaints you will put up the tower to "get the antenna up and away from their houses." And tell them if there are any complaints about a friggin' piece of WIRE then what have you got to lose by putting up the beam anyway?
Keep in mind - you only live once. Who do you want to be happy in your paranoid neighborhood, you or your lousy neighbors?

Owen Duffy wrote:
> Gene, IMHO the terms "constructive interference" and "destructive
> interference" are poor terms.

They are accepted well-defined terms in the field of antenna
radiation. NEC antenna simulations calculate the amount of
constructive and destructive interference before presenting
the radiation patterns.

Quoting Hecht of "Optics" fame: "The principle of Conservation
of Energy makes it clear that if there is constructive interference
at one point, the 'extra' energy at that location must have come
from elsewhere. There must therefore be destructive interference
somewhere else."

You seem not to understand that the constructive interference that
results in the gain of a Yagi antenna, must obtain that energy from
an equal amount of destructive interference in another direction.
If constructive and destructive interference didn't exist, all
antennas would be isotropic. Think about that.

You already no doubt understand constructive and destructive
interference in the radiated fields of antennas. Just broaden
that understanding to transmission lines. The destructive
interference toward the source in a Z0-matched system is
identical to the destructive interference off the back of
a Yagi antenna. The constructive interference toward the load
in a Z0-matched system is identical to the constructive
interference off the front of a Yagi antenna.

> The in-phase and out-of phase, equal amplitude cases are a very small
> subset of the real world cases ...

Absolutely not true for amateur radio systems with antenna
tuners. The function of the antenna tuner is to bring the
forward and reflected waves into phase (or 180 degrees out
of phase). All matched amateur radio antenna systems fall
under the category of in-phase (or 180 degree out of phase).
In either case, the cosine of the angle between the two
voltages is zero, reactance is neutralized, and V*I*cos(0)
is 100% in watts, 0% in vars.

> The usage here appears to derive from a certain person's need to use
> terminolgy and examples from other electromagnetic radiation applications
> to describe transmission lines.

No matter what your opinion, Owen, EM waves *are* EM waves.
They all obey the laws of physics. I suspect you know a lot
more about constructive and destructive interference than
you realize at the moment. Antenna gain depends on it.

Cecil,

If you actually understood the way the Poynting Theorem works, you would not waste your time worrying about ExB. It provides no useful information in support of your wacky energy flow ideas.

Hint: Although the Poynting vector is defined as ExB, this is only a flux. If you are interested in information relating to conservation of energy it is necessary to integrate over a closed volume. The total integral of the flux over the surface of that volume is then equal to the rate of change of energy within the volume.

In your favorite example, where energy is coursing back and forth along the two directions of a lossless transmission line, this integral over any volume you choose will be exactly zero. Even if you could separate the forward and reverse waves the Poynting vector energy calculation would still come out to exactly zero for each component as well as the sum of the components. The same amount of energy exits the integration volume as enters it. Only in the case where there is a source or where there is loss will the Poynting energy calculation yield a non-zero value.

If you want further information you can check advanced textbooks such as "Classical Electrodynamics" by Jackson or "Principles of Optics" by Born and Wolf. I am sure there are many other references, but those are the two I check almost daily.

Cecil,

OK, we are getting somewhere. According to the equation, we know that interference has the same units as irradiance. Interesting. Does that mean that interference doesn't work for fields? Are there multiple definitions for interference?

I am not at all ignorant of what Hecht has written, but I will admit to being ignorant of the exact choice of words he uses.

> Cecil, would you state the superposition principle as you know it?

I'll just quote Hecht on that. He gives the three dimensional differential wave equation and follows it up with a linear combination of individual waves in an equation that cannot be reproduced here and says,

"Known as the *Principle of Superposition*, this property suggests that the resultant disturbance at any point in a medium is the algebraic sum of the separate constituent waves."

The unreproducible equation essentially says that the total wave function is equal to the algebraic sum of the individual wave functions.

Hecht goes on to treat the forward wave and reflected wave as the "separate constituent waves", something that we have been told by the "reflected waves don't exist" gurus on this newsgroup, is an invalid thing to do.

It seems to me that the superposition principle gives us permission to consider the forward and reflected waves separately and "algebraically sum" the results. That is exactly what the S-Paramater analysis is based upon. The S-Parameter analysis considers a1 to be the incident forward wave and a2 to be the incident reflected wave. They are treated separately and then "algebraically summed".

Forward and reflected waves are easily separated by a
circulator so their existence is difficult to deny.

So net energy equals zero? So what! We are NOT discussing net
energy here. We are discussing the forward Poynting vector
and the reflected Poynting vector as described in "Fields and
Waves ...", by Ramo and Whinnery. The Superpositon Principle
gives us permission to do so and the final result is identical
to any other valid analysis. Why are you guys so irrationally
afraid of the wave reflection model? What is your ulterior
motive in denying the existence of reflected waves during
steady-state? It has seemingly turned into a steady-state
religion administered by the steady-state high priests.

Cecil, this is not a complete definition, and you have not related it to the subject under discussion, tranmission lines, and the quantities that are being discussed.

To my mind, there is nothing in YOUR definition above (it is not Hecht's, it is your partical quote and elaboration) that states that it is valid to sum energy waves or power waves (whatever those terms mean) as you seem to want to do, or to treat them independently if that is what 'separately' means as you use it, or the specifics of what quantities are summed.

Several people have been freely writing expressions that take the algebraic sum of phasor quantities Vf and Vr, and If and Ir. You are citing and partially quoting obscure sources not directly relevant to the subject to justify your summation of energy waves or power waves or whatever you are calling them today.

Sit down and write a complete definition of your knowledge of the "Superposition Principle" as you understand it using quantities encountered in a transmission line analysis, like voltage, current, power.

My IEEE Dictionary is 130 miles away so I cannot look
up the technical definition for interference. The units
of irradiance are watts per unit area. In a transmission
line, we can consider the unit area to be constant and
simply drop the units of area. The resultant "irradiance"
equation for transmission line power is:

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

2*SQRT(P1*P2)cos(A) is the interference term in watts
where A is the angle between the two interfering fields.

This is all explained at: http://www.w5dxp.com/energy.htm
If the above equation is followed, adding powers is easier
than superposing voltages and then calculating power.

Is this what you mean by 'algebraic sum' as in your words 'resultant
disturbance at any point in a medium is the algebraic sum of the separate
constituent waves'?

Here is the way one sums the power in two energy waves. This
is one of the things that Dr. Best, ve9srb, got right in
his Nov/Dec 2001 QEX article, "Wave Mechanics of Transmission
Lines, Part 3: Power Delivery and Impedance Matching". This
article is what got me to thinking along my present lines.

Ptotal = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where A is the phase angle between the two energy waves.

This is the same as the irradiance equation from the field of
optics and applies perfectly to transmission lines. The first
time I saw the equation was in Dr. Best's QEX article so I
certainly cannot take credit for it.

All this information has been available on my web page for
years.

Of course not. That statement of Hecht's applies to vector
(and phasor) fields. Powers are scalars and must be treated
accordingly.

Probably should be written 2*|SQRT(P1*P2)|*cos(A) to
satisfy the purists. The sign of the interference
term must match the type of interference which is
determined by the sign of cos(A).

The third term in the equation is the interference term.
A positive value indicates constructive interference.
A negative value indicates destructive interference.

All,

This is a real world "what is going on" question. The antenna is a 'screwdriver' on a 3 foot stand in the back yard. The earth ground is normal loam, the original soil was forest. The feed cable is about 130 feet 50 ohm coax that measures to be in good shape. The ground system is 8 wire radials between 30 and 60 feet in length.

The measurement tool is an HP 8407a network analyzer and an HP 8601a sweep generator. The frequencies of interest are from 3.5 to 4 MHz. As the antenna is moved from resonance at 3.5 MHz to 4 MHz the return shows a marked difference. It varies between -24 db and -50 db. The pattern is irregular, however it is repeatable.

The antenna design is a coil that moves up or down across copper fingers. As the coil moves those fingers contact more or less of the coil and change the impedance.

What could cause the variation in return across a relatively narrow band. A return of -24db is relatively small, an impedance very close to 50 Ohms and an SWR about 1.135. A return of -50 db is less then 1.01 SWR and represents a small change in Z, however a change non the less.

I can think of three potential causes for this change:

1. variations in the coil change Q

2. variations is the finger to coil connection change R

3. variations in the ground radials.

Are there others?

Thanks - Dan

Dan, 24 dB return loss is about as good as you can possibly get
for any type of design: matching network, filter, you name it.
Anything better is just pure luck. In any design you always
get some very deep return loss notches. They could just as well
be minor errors in network analyzer calibration, and how
accurately your standards are characterized.

Please reference Chapter 9, Interference, in "Optics",
by Hecht, 4th edition. The two interfering waves are
traveling in the same direction. The associated
powers exist together at a point of interference.

> immediately would go a long way toward countering how big an eyesore
> it really is.

Andy adds:
Well, I don't have neighbors but I have a wife who does not see the
existence of outside antennae as an art form. We just moved into
a new house 2 years ago, and recently I decided to get all the ham
gear working again......
I put the dipoles, and a 2 meter gnd plane, in my attic near the
top
of the roofline on the inside.
They work just fine, low SWR, and receive and transmit well......
Being
under a half inch of plywood doesn't alter the characteristics
significantly.
If your roof line will accommodate this, it is a thought....

Also, rather than dipoles, a loaded flagpole or TV antenna mast
would
be another option.....

No way your neighbors could possibly be as picky as my wife.......

I realize that there may be a difference of opinion about mounting
an
antenna in the attic versus on top of the roof, but I've never been
able
to tell any difference in performance for dipoles and gnd planes....
The measure I use is : " When the H F antenna is connected to the
receiver
input, if the ambient noise level rises appreciably, the antenna is
working
just fine (noise level is due to the cosmos and not receiver
generated) "

Andy asks:
I have a quick question about the number of microwatts that an antenna will extract from the air and put into a known load.

Assume a 70 ohm perfect antenna used for receiving a signal....

Preceived = Pwr density (watts/sq mtr) X Capture Area (sq mtrs)

Is this the power that the 70 ohm antenna will put into a 70 ohm resistor connected to the antenna (as the load), OR is half this power dissipated in the antenna and the other half sent to the load (considering the antenna as a Thevenin generator)....?????

Thanks for any discussion on this. I know it is simple, but I would like to hear what others have to say about it....

The short answer is that the product of impinging wave power density and capture area equals the power dissipated by the load, assuming a lossless antenna and matched load.

A lossless antenna won't dissipate any power applied to it. So it certainly won't dissipate half, or any, of the power from the wave.

You won't find "capture area" in many texts, but when you do, it'll be another term for the much more common "aperture". Among variations of this are "aperture", "effective aperture", "maximum effective aperture", "scattering aperture", "loss aperture", "collecting aperture", and "physical aperture". The aperture is the ratio of power delivered to the load, to the power density of the impinging wave. If the antenna is lossless, terminated in the complex conjugate of its transmitting feedpoint impedance, and oriented for maximum response to the wave's polarization, the effective aperture, maximum effective aperture, and scattering aperture are all equal, and represent the cross section of the power in the impinging wave delivered to the load.

Kraus's _Antennas_ is a good source of information about this topic.

Reverse psychology. You make sure they're glad you're a ham.

You help one neighbor correctly wire an outside GFCI receptacle because you know how and he doesn't (and he's already tripped the branch breaker six times with his attempts); you give another neighbor your old CB antenna for his boat (and you were done with it, anyway); you put an F-series connector on a piece of RG-6 so the next neighbor can hook up her cable modem in a new room (and she's a babe, too); you reflow the solder pads on a PC-mount RCA jack because your neighbor's kid keeps pushing the plug of his video game into the TV too hard (three times so far -- last time I gave it back with two short pigtail jumpers so he wouldn't do it again.).

Four neighbors, four stories, all true and there are more. Heck, I could put an air-search radar antenna on my roof and they wouldn't say anything!

Further to Roy's notes, keep in mind that for most antennas, you cannot determine the Effective Aperture Area (or Capture Area) using a ruler. This effect is demonstrated if you consider that a short low loss dipole with low loss matching has an Effective Aperture Area nearly as large as the much larger half wave dipole.

For many purposes, you would determine the Effective Aperture Area by determining Gain from Directivity and Loss, thence Effective Aperture Area from Gain and Wavelength.

It's hard to believe that anybody, anywhere sells a "weatherproof" unit
that uses bare bulkhead SO-239s and terminal blocks... but that is what
every company, everywhere seems to do. They are easy to manufacture, but
they dump all the weatherproofing problems onto the customer.

Until someone starts to sell remote boxes that use sealed lead-throughs
with tails of cable, and in-line connectors that can be made truly
waterproof, I will continue to make my own.

Hi Dan,

There is the 130 foot radial (the transmission line's unchoked
shield).

There is also an unreasonable assumption that this slight variation is
meaningful.

You would do better (per the advice of Reggie, in times past) to
invest the wire in those 8 radials to more radials that are not much
longer than the radiator is tall.

Soil from a former forest is not particularly good soil; and it isn't
particularly relevant to the outcome except as a large resistor (which
may more than explain the good match).

Thanks for all the advice. I haven't received any comments from the wire laying on my roof yet. Several neighbors already know I'm a ham and have no problem. I've told them about how I can really help out during an big emergency. The two most uptight residents (one across the street and one next door) are planning on selling their places this summer. I figure if I can get a wire in the air, I can always tell the new occupants, "I've had antennas up since before you moved in."

I do like the idea of being the neighborhood fix-it guy. I want to spread goodwill, not spite. They all know that I am a beekeeper (no hives on the property), and will take care of any wasp problems they have. Getting rid of a bald-faced hornets nest earns some big respect from the neighborhood boys. More so when I don't wear the white suit!

Also, we're having more young families (like mine) move in. It would be nice to build some interest among the young boys. Right now the only interest my 8 and 6-year old boys have is playing with the FRS. I'm in no rush.

It's a shame you have only one reference that is so impoverished as to
restrict itself to this "same direction." Otherwise, you would have
been able to answer Keith's question without asking him to figure out
what you couldn't. It is, after all, a commonplace of superposition
(that is what this thread is about, isn't it?) - or are you the
doubting Thomas this thread's subject alludes to?

The stumbling over absolute values was funny too. I was wondering who
was going to pull that rug.

This is getting way too confusing. After adding absolute value
to clarify which of two possible roots is being used (though
without any rigorous rationale), it turns out that different
formulae are needed depending on the direction.

So some times
Ptot = Pf - Pr
while at other times
Ptot = P1 + P2 + Pfudge

Are there other conditions we need to be aware of when computing
Ptot?

How does this align with your previous quote?
"Known as the *Principle of Superposition*, this property
suggests that the resultant disturbance at any point in a
medium is the algebraic sum of the separate constituent
waves."

Neither of the equations is the "algebraic sum".

...Keith

How does this align with your

and hence my recommendation to abandon power as a useful method of analyzing
waves in transmission lines. power is a scalar, you can't add power without
resorting to digging out the phase angles that come from the current or
voltage waves. so really that p-total equation is what happens when you add
2 current waves and then convert back to powers... you cancel out a whole
bunch of Z0 terms but end up having to keep that ugly phase related factor.

and yet again you cross up terms... voltage and current are on wires. E and B are fields between or outside of wires. while they can be handled similarly they should not be compared directly as you are asking. and yes, there is at least one very good example of a voltage without ExB... just charge a balloon up with some stray electrons and leave it alone long enough to reach steady state... voila, E with no B. Please do this experiment and reply when you have truly reached steady state.

and hence if you start with the capture area by definition all the power is
sent to the matched load. basically you measure the capture area by
measuring the power in the load and dividing by the power density.

the real important thing though is that the match is near perfect at either
1.135:1 or 1.01:1, so stop playing around and put some power to that sucker
and make some contacts! remember, 'too low an swr can kill you'! or at
least keep you off the air for as long as you are tweaking it.

Andy writes:
Thanks to all for the discussion..... I have used the results of
these
calculations for many years but wanted to see what explanations I
would
get from others who also have experience in these matters.....

For capture area, I use " Gee lambda squared over four pi ",
which
is the standard definition for a well behaved antenna with a main
lobe, and it has always worked well for me. I don't remember doing
the
derivation for this, but I'm sure I must have done it in the past
(olden times)...

Yet, I was not comfortable with what seemed like a discrepancy
between
"all the extracted power goes to the load" and the proposition that
the
cosmos and antenna acted like a generator and therefore had an
internal
impedance which must be Thevenin matched for max extracted power....
I resolved it, in my mind, by ignoring the latter explanation
(grin)..... and
apparently it was the correct thing to do...

So, thanks again, guys.....

Andy W4OAH

Waves traveling in opposite directions have no effect
on each other. The result is standing waves.

> while at other times
> Ptot = P1 + P2 + Pfudge

Actually, Ptot = P1 + P2 +/- Pinterference

Coherent waves traveling in the same direction have an
effect on each other. As quoted from "Optics", the last
term in the irradiance (power) equation is known as the
"interference term".

> Neither of the equations is the "algebraic sum".

Of course not, power does not follow the superposition
principle. The irradiance (power) equation is the correct
way to add the power scalars that exist in superposed waves.

I'm posting an energy brain teaser problem under a new
thread by that name. Try solving the problem by conventional
methods and then try an energy analysis.

With as little effort as possible, determine Pfor2 and Pref2.

Given: Pfor1 = 100 watts, Pref1 = zero watts
[(Z02-Z01)/(Z02+Z01)]^2 = 0.5

100w---Z01 ohm line---+---Z02 ohm line---unknown load
Pfor1--> Pfor2-->
<--Pref1 <--Pref2

Cecil,

This is a perfect example of how the messages get so confused around here. You cannot simply ignore dimensionality, units, vector vs. scalar, etc. That leads to really silly conclusions like expressing interference in the same units as irradiance.

I don't know if dimensional analysis is still taught these days, but way back when I was taking science classes it was often stated that the very first thing to do when attempting to solve any problem was to make sure that all of the dimensions and units matched up. The numbers mean nothing if the equations are wrong. I suspect a few others in this newsgroup had similar training.

Cecil,

I guess I was not quite clear. I don't care if you are talking net energy, gross energy, with or without circulators, or anything else. As long as there are no sources or sinks of energy in the region of interest, the Poynting vector tells you absolutely nothing about energy balance or conservation of energy.

You could have a completely incorrect analysis of forward and reverse waves, and the Poynting analysis will not reveal the error. The required integral will still come out to exactly zero.

Radio amateurs and radio charlatans love to talk about Poynting vectors, but it is obvious that most of those folks simply don't understand the full picture. Just forget about ExB (or more commonly, ExH). It is completely useless in support for the typical RRAA discussions.

That's not the point at all. The question is pretty
simple. Does the principle of superposition give us
permission to analyze the individual forward and
reflected waves separately and then superpose the
results? If you say "no", then you don't accept the
superposition principle. If you say "yes", then
please stop harping that the only valid way to solve
a problem is your way.

Cecil,

I have said many times that you can choose to analyze the individual components or you can analyze the superposed combination, i.e., a standing wave. It is purely a matter of mathematical convenience. However, if you get different answers, including more or less completeness, then you have made an error. That is the essence of superposition. If that property was not true, then superposition would be of little value.

It is rather ironic that you are accusing *me* of allowing only one valid method when I have repeatedly stated a flexible approach. Is that some sort of debating technique you learned?

Are you instead seeing a reflection of yourself? Is this some sort of mirror trick?

My experience with a screwdriver antenna is that the bandwidth vs vswr is not as good as he is showing. My bet is that the ground is acting pretty much like a dummy load making the SWR look real good. He could probably use a good ground system before he tries talking . If I were using a screw driver antenna as a base antenna I would consider seriously increasing the length of the radiator.

An energy analysis yields exactly the same results as any
other valid method of analysis and is often much easier.
There are no "different answers", yet you imply there are.
An energy analysis obeys all of the principles of physics.
Optical physicists have been solving energy analysis
problems for centuries.

It's a simply yes/no question: Does the analysis of the
forward wave and reflected wave separately abide by the
rules of the principle of superposition? The answer is
obviously "yes" because identical results are obtained
using either method.

> It is rather ironic that you are accusing *me* of allowing only one

Stated, yes. Practiced, no. I don't attack your methods,
Gene, yet you repeatedly attack other valid methods that
yield results identical to yours with less effort. You
only pay lip service to your "flexible approach". Your
practiced approach is pretty narrow-minded - your way or
no way.

Pretty much the same story here. occasionally. I get the new neighbor
that says something but the rest will put 'em straight. A little guilt
goes a long way too. I was accused of causing interference on their
TVs but I knew it wasn'.t me because I was on-the -air when they were
having problems. It turned out the guy that was complaining the
loudest had an antenna pre-amp on his tv that was breaking into
oscillation. i fed him a little humble pie but not too much. Since
then no problem.

Wires are generally not noticeable at all and your neighbors probably will not even know, even if strung in the front yard, especially if feed lines are not hanging down too obtrusively.

I live in a neighborhood with no restrictions and have a 284' delta loop of #16 copper clad steel line between three trees (one tree in my front yard is my neighbor's with his permission), and unless you look you wouldn't know it was there. When a neighbor two houses away said she thought she heard my voice on the answering machine, I explained the situation (cheaply made, no filter answering machines) and promptly ordered her a telephone line filter which worked perfectly. She wanted to pay for it and I refused, believing the $30 bought a lot of good will. (I actually have been here longer than any of them and not the oldest by far.) Your offer to help sort out any problems goes a long way, but no need to go around asking.

I wouldn't worry at all about a wire and if anyone complains of RFI problems, help sort it out and eliminate it. After all, you may be their only contact to the outside some day in an emergency.

The part of the antenna that radiates the most
is the part below the loading coil. On my HS-1600,
that section is 3 feet long. If you want to
dramatically increase your radiated power, add
another three foot section under the existing one.
Since you don't have to contend with the 12.5 foot
mobile antenna limit, make that bottom section
below the coil as long as possible.

If EITHER line has loss, the problem statement is incomplete, at best.

If the lines are lossless, Pfor2=175W, and Pref2 is obvious.

And it's a REALLY weird way to state the impedances. It looks like someone was interested in the impedances of the lines after thinking to make some measurements of VOLTAGE and maybe CURRENT along those lines and couldn't quite figure out how to get there.

How do we KNOW that Pfor1 is 100 watts and Pref1 is zero?

How do we KNOW that line 1 and line 2 each have UNIFORM impedance?

Simply stating it as a brainteaser doesn't make it relevant to the problems hams are faced with in line-matching situations. In most cases, hams ASSUME they know the impedance of the line they are measuring, whether they realize it or not. That is, they'll use a bridge to make a measurement, and the bridge is calibrated for use at a certain impedance (commonly 50 ohms). If the line isn't that impedance, the measurement will be in error. Just because someone measured 100W forward and 0W reflected on line 1 doesn't make it so, and honestly, that's a much more interesting problem to me than this easy "brainteaser."

Cheers,
Tom

A strange assertion given that in another thread your energy
analysis was incapable of producing any result while alternative
techniques could readily answer the question.

Yes, assume the lines are lossless, but I don't think
that is the correct answer.

> And it's a REALLY weird way to state the impedances.

Yes, to get people to think outside the box. Since the
Z0s are unknown, the voltages and currents are also
unknown, yet there exists a solution to the problem.
This is the typical kind of problem that my EE professors
used to give to the classes at Texas A&M to try to get
us to use our gray matter.

Cross-posted to: sci.electronics.design,sci.electronics.basics,rec.radio.amateur.antenna

Bill ...

I would bet that most of the "confustion" comes from the conditions people put on their answers to the question.

Some postulate a "tuner" between generator and load.

Some postulate a specific internal impedance of the generator.

Some postulate a specific length of feeder line (either lossless or resistive, which is another parameter in and of itself).

Some postulate lots of other stuff, almost all of which is valid in the context of their answer.

What exactly do we mean when we say that we have a "100 watt transmitter"? What we are actually saying is that the transmitter will cause a resistor of a specific value to dissipate 100 watts of energy when tied to the transmitter output port and the transmitter keyed. Let's not muddy the waters up by asking if we are talking about peak power, PE power, average power, or whatnot. Let's just assume an unmodulated carrier putting out a constant power into the resistor that gets just as hot as when 100 dc watts (E*I) is pumped into it from a battery.

What value resistor? Whatever the designer/engineer/manufacturer specifies. 32 ohms? Sure. 50 ohms? No problem. 300 ohms? Certainly. Any competent engineer can give you a specified power into a specified resistive load.

The crux of the question becomes, "What happens if my transmitter is specified into a 50 ohm resistor and I put a 100 ohm resistor as the load? How much "loss" do I get (or another way of asking that same question is how much power is dissipated in the 100 ohm resistor)?"

The answer is that it is impossible to tell without making the measurement. That may seem like a "wiggle" answer, but the truth of it is that the output stage design of the transmitter will dictate how it handles a "VSWR load". In some output stages, the output voltage will increase to the point of nearly driving 100 watts into the 2:1 VSWR resistor. Some will shut themselves down with a protection circuit. Some will go into parasitic oscillation. Some will fry the output devices.

Now increase the magnitude (and probably the sign also) of the problem to toss in a complex impedance instead of a resistive load and the confusion factor goes up rapidly. What DOES that output stage do when the load has an inductive component? Or a capacitive component? And both a resistive component and an imaginary component that varies with frequency?

The simple answer to your question outside the "laboratory environment"
where everything is nicely matched and the internal impedances are set "just
so" is that there IS NO SINGLE RIGHT ANSWER to this simple question.

And that is most probably the cause of your confusion.

Jim

I found out later that it wasn't anti-glare glass.
It was anti-reflective glass. Out of ignorance, I
just chose the wrong word. However, everything I
said was true about anti-reflective glass. A 1/4WL
thin film acts virtually the same way a 1/4WL series
matching section acts and reflections are eliminated
through wave cancellation. Incidentally, your attempt
at superposing powers was why your reflections turned
out to be brighter than the surface of the sun. If
you had instead used the irradiance equation, your
result and mine would have been identical - reflections
eliminated.

Hi Dan,

To be precise, EVERYTHING is the radiator. The unchoked line, the vertical to the coil, the coil, the whip above the coil, AND the radials.

What is of concern, is what is called the current node (I'm about to embrace that tarbaby called standing waves) whose placement can have a very significant impact on the directivity (another tarbaby of "gain" raises its prospect here) of the antenna.

The higher the coil resides in the vertical element, the more linear distance beneath it is available to that current node, and from this, a greater signal out. There is a point of diminishing return (an economics term, not a radiation term) where raising the coil ever higher brings no further gain (both a pun to fulfill the economic basis, and a literal result of RF). You can reclaim more gain from a high coil by adding a top hat which serves to extend the whip above the coil. Hence there is a generally acknowledged rule of thumb that the coil resides somewhere between one half way up to two-thirds the way up of a simple vertical. You may note that your antenna attempts to conform to this model in some sense (for instance, it is not a base loading which is the poorest configuration).

Cecil,

You have argued with me many times that my preference of analyzing standing waves is insufficient; that there is more information contained in the two component traveling waves than in the standing wave. Superposition says that is not correct, but I don't suppose you will accept that.

However, you are in luck. This is Burger King Day. Have it your way.

I think I will drop out of this thread. Feel free to call yourself the winner. Also, go right ahead and give interference the unit of

watts/meter2 along with all of the other misinterpretations from your guru-authors.

I have some anti-reflective glass, Richard. It
does a reasonable job of wave cancellation even
under less than ideal conditions with ambient
light.

Our previous example involved an ideal laser and
an ideal 1/4WL coating of thin film. The index
of refraction of the thin film material was
exactly the square root of the index of refraction
of the glass. Those are ideal conditions for 100%
wave cancellation of reflections as anyone in
the field of optics should know.

No, you have it wrong. All I have ever done is defend
my method of analyzing forward and reflected waves
separately and then superposing while you have done
your best to discredit that approach. You have said it
is an invalid approach and tried to prove it by
asserting that standings waves are completely different
from traveling waves because the phase has disappeared
and is gone forever. Your exact words:

>> Phase is gone. Kaput. Vanished. Cannot be recovered. Never to be
>> seen again.

You cannot have it both ways, Gene. If, as you say,
phase disappears from standing waves, then they are
quite different from traveling waves (which they are).

In a standing wave, the phase is constant.
In a traveling wave the phase is changing.

In a standing wave, the amplitude varies.
In a traveling wave the amplitude is constant.

In a lot of ways, standing waves and traveling
waves are opposites.

Hi Dave,

This is not a very compelling reason for method that has a wide application in optics; Cecil has no real experience in this field, and it shows frequently, but the math is quite common. It relates, peripherally, to Keith's advice to investigate lattice diagrams, but Cecil no doubt hesitates to trod this path that leads to the destruction of his other favorite, failed example of anti-glare glass.

'standing' waves aren't waves at all, they are figments of your instrumentation. simple instrumentation (read light bulb and loop of wire) that was originally used to 'tune' antennas could detect only the peaks and dips of the superimposed forward and reflected currents... because these 'looked' like waves that stood still on the line when you plotted them they became known as 'standing' waves. and this also led to the horrible use of the 'standing wave ratio' as a measure of how good an antenna was matched to the feed line. all of this over the years has led hams to consider 'standing' waves as a real thing when it is really just a consequence of the superposition principle. We would all be much better off if someone many years ago had labeled the first 'SWR' meter in units of db for measuring return loss, or v-forward/v-reverse, or some other real physical unit. not that the meter would function any differently, but we would all be better off understanding what is really being measured!

Yep, that's another way they are different from
traveling waves. :-)

Actually, it showed perfectly the 100% cancellation
by two waves each of equal magnitude and opposite phase.
It was your superposition of powers that was at fault
and you apparently don't even realize your mistake.
Do you want to go through it again?

Have you tried the brain teaser I posted? It is a
lot like non-reflective thin films.

Richard, I don't consider the AT/ATR tube relevant to the discussion of re-reflection of reflected power
incident on the output of a pi-network in an RF TX.

>There is absolutely no example of interference that does not rely on a
>load to reveal it.

If what you just said is true, then how do you explain nulls in a radiation pattern of an antenna having more
than one radiator, for example two verticals spaced 1/4 wl and fed in quadrature, thus creating a cardioid
pattern with a total null in one direction in azimuth? If the null was not created by interference between the
radiations from the two verticals, then how do you explain the formation of the null?

Amusing. You don't really know anyone of them, do you? Certainly none who have to live with the invalidity of this sophomoric treatment.

Your own model showed the falsity of this supposed 100% cancellation. As I said, your visiting the topic of Lattice diagrams is not even on the horizon, and behind it, Fresnel's equations are even more remote. (I can well imagine you flipping through the index to find those pages to presume their understanding, your Xeroxing other's work is apparent.)

Like I said, your are quite ignorant to the matters of Optics. RF runs a poor second, as your professional life in binary design has corrupted your thinking.

How will they know what it is?

If you're sensitive to appearance, I personally use The Wireman's #18
AWG stranded wire with black insulation for an 80 meter dipole hung
from 3 trees. A screen door spring at each end inserts enough give to
keep the swaying trees from snapping the wire.

The whole setup is pretty hard to see, unless you're looking for it.

The Wireman also sells a #26 stranded, if you're really looking to be
invisible.

In general, in real-world ham problems, it is far from given that we know that the impedance of a line is really uniform. We don't even know the impedance for certain. There have been any number of postings here in the past where someone can't figure out what the impedance of some unknown line is, and I'm sure there are far more instances of people ASSUMING that RG-8-type line is 50.00 ohms. It practically never is. (But it also practically never MATTERS for typical ham applications.) WHY should I believe you know how to measure the impedance of a line, and that you know how to calibrate a bridge to that impedance? I'm NOT saying that you DON'T know how, only that I need convincing. I've seen plenty of evidence of those who haven't a clue about either around here, so I prefer to start from the point of view that any reported measurements of "forward and reverse power" are likely to be flawed.

Since you "know" that the meter is calibrated for the impedance of the line, you must know the impedance of the line. Why didn't you just give the line impedance? Is it possible to determine the forward and reverse powers by measurement of a real TEM line of unknown impedance without measuring everything you need to know to find the line impedance (and in fact to do so nearly trivially)?

Yeah, I shouldn't try to work these things in my head before breakfast. Pfor2=200.

Cheers,
Tom

Well, let me do you one better. It is far from given that
you exist. Please prove that you exist before we go any
farther. (I have rarely heard such a strange argument
against mental exercises as you presented above.)

Seems you would be completely opposed to exercises using
lossless lines, huh? I can hear it now: "It is far from
given that a transmission line can be lossless." Yes, it
is, but textbooks are filled to overflowing with such
examples.

Then someone could have converted to voltage, wasted a
lot of time, and avoided the new experience of dealing
100% with power. I'm glad you woke up and figured it out.
See how easy that was? BTW, congratulations on being the
only one (so far) to figure it out.

Cecil, the set of statements above is not true in the general case.

You seem to want to talk principles, then make statements without
qualification that are not true in the general case.

Its all very confusing!

Owen

> principle.

I've reviewed some of your writings and you have said this
at least as far back as 2001. This is good.

So why did I think otherwise? I think it is your reliance
on Ptot = Pfor + Pref. I see this as an expression from
superposition much the same as Vtot = Vfor + Vref, but I
gather from the paper on your web site that you do not,
rather you see it as an expression of conservation of
energy.

>From re-reading your paper, it seems that your thinking
all derives from trying to satisfy the principle of
conservation of energy. This is good. There is general
agreement that energy is conserved.

But them I am confused with your ready acceptance of
Ptot = P1 + P2 +/- Pinterference

Given a P1 that actually exists and a P2 that actually
exists it seems to me that Ptot must equal P1 + P2.
Anything else would fail to satisfy the principle of
conservation of energy.

To make the expression work, +/-Pinterference must
be creating or destroying energy. Given my understanding
of the physical world, this seems most unlikely.

Can you elaborate on how +/-Pinterferance creates or
destroys energy while still conserving energy?

Hi Andy,

As you mentioned, Thevenin does apply, and your effective area formula is correct (gain w.r.t. isotropic radiator). So a thin halve wave dipole antenna has an internal resistance of about 70 Ohms, and half the power is lost, but not as heat in the antenna. The driving (incident) EM-field induces voltage with causes a current to flow in your 75 Ohms load (and in the antenna).

The current that flows into the antenna structure (two bars) radiate. So part of the incident field is reradiated by the dipole. It doesn't matter whether the antenna current is caused by a transmitter or

incident field. As your dipole delivers 1mW to the load, also 1mW is reradiated into space. Behind the antenna, the reradiated field cancels (partially) the incident field (causing a shadow effect).

When you remove the load, the output voltage at the antenna doubles and the current in the dipole reduces to a low value, hence less power is reradiated. When you short circuit the dipole, the current will double (w.r.t. to the matched situation). This will also happen to the current in the bars forming the dipole. As the current has been doubled, the reradiated power is 4 times higher (w.r.t. the matched situation).

The reradiated power can be detected. Radar and passive UHF RFID use the reradiated power. For example in UHF RFID, the chip on the RF tag changes the load to the dipole (that receives power from the interrogator), and controls the reradiated power. In this way the ID of the tag is transmitted from the tag to the interrogator (the tag has no battery present).

The more gain you have in your antenna, the higher the reradiated EIRP in the direction of maximum gain.

I hope this clarifies the antenna internal resistance.

Best Regards,

Wim

Not if there's a lossless tuner.

In which case it's not truly "lossless" (and after breakdown becomes VERY
lossy).

> So why did I think otherwise?

Because you have been told by others that I was superposing
powers. It was a false malicious statement.

> But them I am confused with your ready acceptance of
> Ptot = P1 + P2 +/- Pinterference

If it is good enough for Eugene Hecht, it is good
enough for me. That is essentially the irradiance
from optical physics.

> Given a P1 that actually exists and a P2 that actually
> exists it seems to me that Ptot must equal P1 + P2.

No, that is superposition of powers, something that is
not valid. The only time that Ptot = P1 + P2 is when
the phase angle between the voltage is 90 degrees and
the interference term is zero.

> Anything else would fail to satisfy the principle of
> conservation of energy.

No, Ptot = P1 + P2 violates the conservation of principle
if the phase angle between V1 and V2 is not 90 degrees.

> To make the expression work, +/-Pinterference must
> be creating or destroying energy.

No, there are two Ptotal's, one in each direction in
a transmission line. If a certain value of destructive
interference exists in one direction then an absolutely
equal value of constructive interference has to exist
in the opposite direction in the transmission line.
Since destructive interference = constructive interference,
no energy is created or destroyed.

All this is explained in my energy article.

> Can you elaborate on how +/-Pinterferance creates or
> destroys energy while still conserving energy?

Transmission line energy is neither created or destroyed.
What is lost in one direction is gained in the
opposite direction. If reflected energy is eliminated
toward the source, it must show up in the forward wave
toward the load. I cannot explain it any better than

these web pages.

if by 'changing' you mean 'changing with displacement or position', to
make these statements true, you must be talking about lossless or
distionless lines. If your entire discussion is premised on this, then
can your methods / formulas solve practical lossy line problems?

Nothing seems complete and self explanatory... so still, I am left
confused.

> Do I need to see you crawl again?

Here it is again. Reflections are eliminated at the
air to thin-film surface.

In the following fixed font diagram, IR is the Index
of Refraction.

```
air | 1/4WL thin-film | Glass
1W Laser---IR=1.0---|----IR=1.222-----|--IR=1.493---...
Ifor=1W | Ifor=1.0101W | Ifor=1W
Iref=0W | Iref=0.0101W | Iref=0
```

Note that I is "irradiance", not current.

Given: The irradiance reflection coefficient is 0.01
at both interfaces. The irradiance transmission coefficient
is 0.99 at both interfaces.

>> Have you tried the brain teaser I posted? It is a
>> lot like non-reflective thin films.

Of course, that's why the feedpoint impedance of a 1/2WL
dipole is not zero ohms. Approximately 20% of the
energy on the antenna is radiated during steady-state.

To answer the question more fully: The title of my energy
article is: "An Energy Analysis at an Impedance Discontinuity
in an RF Transmission Line". Since the analysis is done at
a *point*, what happens somewhere else in a lossy line is
not a consideration. There are essentially no losses at an
impedance discontinuity *point* (or plane).

Hi Walt,

And yet they are relevant to the larger topic of reflection, are they
not? That is their sole purpose after all, they exhibit EVERY
observation you've offered, and without them those observations
disappear.

I use a load. It is exactly like the internal resistance of a
internal resistance where the reflected energy is in phase with the
source. The load exhibits no current flow (a null). Shift the phase
180 and the internal resistance exhibits a dramatic current flow (a
lobe). The energies are there either way. Remove the internal
resistance and nothing conducts EVER. Clearly the internal resistance
(the load in this case) is what reveals interference, not the
energies. In free space they would pass like ships in the night.

If I may add just a simple observation to the exhaustive Wim's explanation, I would say that we generally tend to consider resistors as things that necessarily dissipate power, turning it into heat. That is not always the case.

As a matter of fact, having current in phase with voltage (what we usually call resistance) signify the transformation of electrical power into any form of power, not just heat. For instance:

- an ideal electrical engine (no ohmic loss, no friction) fully transforming the applied electrical power into mechanical power. It looks like a resistor, but no heat is generated anywhere

- an ideal antenna (no ohmic loss) fully transforming the applied electrical power into electromagnetic power. Again it looks like a resistor, but no heat is generated anywhere

.

> to analyze the forward wave and the reflected wave
> separately, or not?

It would appear from the many posts that the consensus is
that superposition is alive and well. It works for voltages
and currents. It does not work for power.

But then I have two questions.

Firstly, in another thread, the solution for the problem
presented required knowing the impedance that the generator
presented to the reflected wave. This is exactly the sort
of question that superposition handles easily: The impedance
encountered by the reflected wave at the generator is the
same as the generator's source impedance. I am curious as to
why you don't want to use superposition to facilitate solving
this problem?

Secondly, the "directional wattmeter" uses superposition
to compute Vf and Vr from which it computes Pf and Pr. You,
like many others seem willing to subtract Pr from Pf to
obtain Pnet. But this would only seem to be valid if
superposition works for power. So why are people who accept
that superposition does not work for power, prepared to
accept that Pnet = Pf - Pr?

...Keith

Andy replies:
Thanks Wim and Tony, for a very well presented explanation of
the Thevinen .... I KNEW it had to coincide with the CAxPdens
numbers, but your post pretty well cleared it up....for me, at
least...

Regarding RFID using re-radiation --- I was the designer of
the TIRIS toll tag system for T I (at 915 mhz) and the method I used
was
to open and short a dipole in the TAG to send data replies to the
Reader.... The specification required an RCS
(Radar Cross Section) change of 180
sq cm at 915, and that was easy to obtain with a dipole and a
pin diode . (Actually, the RCS changed too much for the spec,
and I had to pad it down a bit)......

I hadn't considered that an antenna delivering to a matched load
lost it's power by re-radiation .... DUHHHH!!!.... Been building stuff
for 50 years , and that obvious fact just never dawned on me....
So, thanks again....

Richard, don't you think falsifying postings is getting a
little desparate? As you know, and as indicated by your
posting to which I was responding, the subject was which
square root to use in the irradiance equations, not Fresnel's
equations. I have honestly reproduced the thread above. You
have been caught red-handed cutting and editing in an attempt
to falsify the meaning of my posting. That's a violation of
netnews rules and probably a violation of your ISP's rules.

No, it looks like a resistance, not a resistor. There is one
IEEE definition for resistor. There are two IEEE definitions
for resistance. A resistor with current dissipates power. A
resistance may or may not dissipate power. One definition of
resistance in the IEEE describes a dissipationless resistance.
There is no such thing as a dissipationless resistor.

No, the generator's source impedance is *NOT* the
impedance encountered by the reflected wave. Please
reference w2du's article again.

http://www.w2du.com/r3ch19a.pdf

Forget about the conjugate match and concentrate on the
non-dissipative source resistance being different from
what you are calling the generator's source impedance.
An *active* source creates a source impedance looking back
into the source that is *different* from what you are
calling the generator impedance.

> Secondly, the "directional wattmeter" uses superposition
> to compute Vf and Vr from which it computes Pf and Pr. You,
> like many others seem willing to subtract Pr from Pf to
> obtain Pnet.

One can directly add and subtract powers under certain
conditions. One condition is if two waves are not coherent.
Another condition is if two coherent waves have no effect
on each other. Since the forward wave and the reflected
wave have no effect on each other (except in the human
mind) reflected power can simply be subtracted from from
forward power to obtain power delivered to the load but
that is NOT superposition of powers. It is a simple
addition/subtraction of scalars based on the conservation
of energy principle.

> But this would only seem to be valid if
> superposition works for power. So why are people who accept
> that superposition does not work for power, prepared to
> accept that Pnet = Pf - Pr?

You seem to have forgotten the definition and rules of
superposition. Superposition applies to fields and waves.
Superposition doesn't apply to scalars. Power is a scalar.
Or another way to express it is:

V1 + V2 = V3 (vectors or phasors)

(V1 + V2)^2 = V3^2 (scalars)

V1^2 + V2^2 <> V3^2 (scalars)

It's a pretty simple principle of mathematics. The square
of the sum is NOT equal to the sum of the squares.

Cecil Moore wrote:
> V1 + V2 = V3 (vectors or phasors)
>
> (V1 + V2)^2 = V3^2 (scalars)

In fact, the irradiance (power) equation falls out directly from the above valid equation. Continuing the process:

V1^2 + 2(V1)(V2) + V2^2 = V3^2

V1^2 + 2*SQRT(V1^2)*SQRT(V2^2) + V2^2 = V3^2

V1^2 + V2^2 + 2*SQRT(V1^2*V2^2) = V3^2

Dividing both sides of the equation by Z0 yields:

P1 + P2 + 2*SQRT(P1*P2) = P3

There you have it. The mathematical derivation of the irradiance (power) equation.

This is, of course, for the condition where V1 and
V2 are in phase.

It IS a resistance, but it LOOKS like a resistor because, from the exterior, one has no means to determine whether energy gets dissipated or transformed in some other form.

Andy comments:

Not to make too fine a point on this, Cec, but I , personally,
would consider a perfect 52 ohm antenna to be a dissipationless
resistor..... although, in the cosmic sense, the power that is
fed into it will eventually reside as "heat" in the bowels of the
cosmos.....somewhere......

Actually, ... "heat" is simply EM at a different frequency....
.... Hmmmmm... I see a deep, philosophical discussion brewing
here..... ..

... Me brain hoits......!!!!

"Even better, let me know the TOA of a dipole in free space and how much it varies to that of the same dipole over perfect ground."

If possible, look at Terman`s1955 opus page 882:
"Effect of Ground on the Directional Pattern of Ungrounded Antennas - Image Antennas."

In free space, no reflecting surface is nearby to distort the pattern of a radiator.

Terman gives the familiar radiation of a 1/2-wave dipole in space in Fig. 23-4(a) on page 867.

Terman says on page 883:
"For purposes of calculation, it is convenient to consider that the reflected wave is generated, not by reflection, but rather by an "image" antenna located below the surface of the ground."

The summation of the direct and reflected waves from a horoizontal wire above the earth often has serious consequences as Terman notes on page 885:
"Consequently, to obtain strong radiation in directions approaching the horizontal using a horizontally polarized radiating system, it is necessary that the height of the antenna above the earth be in the order of one wavelength or more."

Terman shows the vertical radiation patterns for a horizontal wire at various heights above the earth in Fig. 23-21 on page 884. Note that half-wave elevation concentrates most energy into a good elevation angle for sky wave reflection at some frequencies and distances.

Best regards, Richard Harrison, KB5WZI

Richard, also consider an open-wire transmission line, equal and opposite currents flowing on each wire, and
no common-mode currents. There is zero radiation, because the opposing fields developed by the current flow
cancel. Are you denying that the zero radiation results from interferece?

Also, consider standing waves on on a line, resulting from the superposition of the forward and reflected
waves, where the maximum amplitude results from constructive interference and the minimum amplitude results
from destructive interference. Are you denying the existence of interference in this case?

Walt

> cosmos.....somewhere......

Yep, a common misconception. The feedpoint impedance
of a standing-wave antenna, like a 1/2WL dipole, is
a *virtual* impedance equal to (Vfor+Vref)/(Ifor+Iref).
It may be a resistance, but it is not a resistor. It
is essentially the same entity as the impedance looking
into a stub. For a resonant 1/2WL dipole the equation
becomes:

Feedpoint resistance = (|Vfor|-|Vref|)/(|Ifor|+|Iref|)

With Vfor at a reference angle of zero, Vref is at
180 degrees. With Ifor at zero degrees, Iref is
also at zero degrees. Thus the ability to add and
subtract magnitudes directly.

Some guru once challenged me to make a measurement
at the shack and tell the difference between a 50 ohm
dipole and a 50 ohm resistor. Told him all I needed
was a field strength meter. :-)

The words "impedor" and "resistor" are reserved for
real physical devices. The words "impedance" and
"resistance" have two meanings and can mean either
real devices or virtual V/I's. So says the IEEE
Dictionary.

Allright, Richard, then where is the load when there are two vertical radiators spaced 1/4 wl and fed in

quadrature, such that their individual fields are omni-directional in azimuth, but when the two fields
combine, a maximum greater than either of the individual fields is propagated in one direction, while a null
results in the opposite direction, negating the propagation of the individual fields in the direction of the
null. What is your explanation of the negation of the propagation of the individual fields when both radiators
are radiating equal EM energy? Are you still denying that interference is not the cause of the modification of
the resultant fields? So I repeat the question--where is the load in this case?

Very good, all accepted, I am now in a position to ask the real
question of "why" where the starting point is acceptable to all.
.
I model a dipole in free space to obtain its impedance, this dipole
was resonant at right angles to the ground and resting on the ground.
I also modelled another dipole over the ground and tipped it over
about 5% of its WL but letting the length grow until the dipole was
resonant over ground (ground means perfect ground as per Mininec) I

then placed this tipped dipole in free space and noted its impedance.
In all cases the impedance in free space was the same though not
resonant! In all cases over ground the dipoles were resonant. Why were
both dipoles over ground resonant? Why did the program model the
dipole at a tipped angle for resonance when given total freedom
instead of modeling a dipole at right angles to ground?
Regards
Art

The V antenna is a terminated traveling wave antenna the dipoles that you have been refering to are standingwave antennas. You are comparing apples and oranges. The best I can tell is that all other references you made to tilt have been perpedicular to the direction of the wave front. The V antenna is tilted in the direction of the wave front, more apples and oranges. Throw in some grapes and pineapple and we will have fruit salad.

Jimmie,
You are way to quick with your answers which means you are not
commited to follow thru in serious thinking. There is a perfectly
logical reason for it
if you are familiar with the study of waves and fields in electro
magnetics.(grin) And there are a couple of people that stand above all
others that will possibly provide as to why it is logical. Stand by
quietly to listen and learn,you don't have to post if you have nothing
to contribute! Read what Richard Harrison has kindly provided and use
that as a solid base to think about
I have worked very hard to get to this particular point in a thread so
as to cut of diversionary talk at the outset. We have an observation,
now we need the explanation.....Should be a very short thread
if we only count contributors with possible explanations as to what
has been observed.
I'll leave it to others to discern who are the real educated
contributors
and who are the lemmings.
Regards
Art

Perhaps Walter you are really serious with the above question!!!!!!
You have two reference planes, the radiator and the plane of maximum
gain(ie. for vertical polarization) Therefor 90 degrees minus the
angle between both planes equal "take off angle".

Art

3499. Some thoughts relevant to measuring Tx eq src impedance

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-01 22:38:43 UTC
From: Owen Duffy <none@no.where>
Message-ID: <Xns990657ED77ECAnonenowhere@61.9.191.5>
Source record: 43815

I am intrigued that many people have attempted to measure the equivalent source impedance of a transmitter with such varying results.

On the one hand is the assertion that a transmitter adjusted for optimum operation is comparable with a linear source, and the source impedance must therefore be the conjugate of the load.

On the other hand is the analysis usually used to engineer a PA that should reveal the sensitivity of output power to small changes in load impedance and therefore an equivalent dynamic source impedance.

Taking a valve amplifier as an example for discussion...

On first glance, the change in peak anode voltage and current is indicated on the anode I/V characteristics by laying an incrementally different load line on the chart and observing the change with peak grid voltage held constant. The deltas then could be used to calculate a dynamic source resistance at the anode. Essentially, the value calculated will be the inverse of the slope of the constant grid voltage line.

The required anode load resistance is the resistance calculated from the fundamental anode RMS voltage divided by the fundament anode RMS current.

These are not necessarily the same value. In fact, the dynamic source resistance is usually much higher than the required load resistance, and the ratio is usually higher for a pentode or tetrode than for a triode operating at the same voltage and current.

So, immediately, there is an apparent conflict with the proposition that the dynamic source resistance and the load resistance are the same.

Many of the experiments to try to prove that the PA is "conjugate matched" have used a valve transmitter with a PI coupler, so let us examine the behaviour of a PI coupler.

I have designed PI couplers for a 7MHz transmitter using the formulas given in Eimac's "Care and Feeding of Power Tubes". The formulas seem to assume that the intrinsic Q of the components is infinite, ie that the components themselves are lossless. This assumption introduces error, but my supposition is that for very small changes in load resistance, the assumption that Qi is very large will not seriously impact the models.

Models were constructed with loaded Q ranging from 8 to 21, and for a range of anode load impedances, the the sensitivity of the impedance presented to the anode to small changes in the nominal 50 ohm external load.

The interesting observation is that a very small decrease in the nominal 50 ohms load can result in a different relative change in the anode load, indeed, it can result in an increase in anode load impedance, and the sensitivity depends on loaded Q and the required anode load resistance.

For example:
-if Ql is 10 and Ra is 1400 ohms, a 1% decrease in the extenal 50 ohm load results in a 0.26% decrease in the anode load impedance; and
-if Ql is 12 and Ra is 1400 ohms, a 1% decrease in the extenal 50 ohm load results in a 0.48% decrease in the anode load impedance.

For this very small change in operating Q, the effect of a small change in external load resistance is quite different on the anode load impedance.

A further set of examples:
-if Ql is 10 and Ra is 1260 ohms, a 1% decrease in the extenal 50 ohm load results in a 0.32% decrease in the anode load impedance; and
-if Ql is 12 and Ra is 1260 ohms, a 1% decrease in the extenal 50 ohm load results in a 0.52% decrease in the anode load impedance.

So, if the PA is "tuned up" to deliver a slightly different anode load resistance (in this case 10% lower), the sensitivity of anode load impedance to small changes in the external 50 ohm load is different.

The modelling suggests that conventional circuit theory can explain some of the experimental results that are otherwise ascribed to some magical behaviour of the PI network.

Owen

Of course he is serious.

There are no planes in free space for a dipole.

The dipole defines a line, not a plane.

Since the pattern of a dipole in free space is a circle viewed from
the end, and a cardioid from the side, there is no plane there either.

You are plain confused about planes.

...

I have a lot of trouble with that one, especially the "must therefore" part. What is "optimum operation"? Is it delivering the most power to the load, or is it delivering the RATED power to the load, at some particular efficiency and level of distortion? I'd claim it's the latter.

There are lots of examples of "optimum" load NOT being "conjugate-matched" load. A typical stereo amplifier has an output impedance that's a fraction of an ohm, but the amplifier is optimized to deliver power to loads in the vicinity of 4 to 8 ohms, most often. The power lines delivering power to a home show a source impedance that's a tiny fraction of an ohm, but with everything in the house turned on, the net load might be as low an an ohm--in rare cases a bit less than an ohm. The load placed on a typical battery is similarly many times the battery's internal resistance, except in the case of a heavy load on a battery near the end of its charge. And lest you think that all sources are optimized for load resistances higher than the source resistance, I can change the feedback on that stereo amplifier without changing the power output stage design, so the amplifier is still best at delivering power to loads in the 4-8 ohm range, but now the output impedance with new feedback is around 100 ohms.

So WHY should we expect a transmitter to represent a source impedance particularly close to the load impedance, or to its complex conjugate?

I've gone through analyses similar to what you what you reported in the remainder of your posting, with an output network whose Q I varied (in the analysis), and come to similar conclusions. Just as you say, Owen, when I do that, it's all clear and not magical at all. And the source resistance can be made to be what I want through feedback, if I wish. In some of the work I do, it's important to have a virtual ZERO impedance at a particular node, but that's generally done using an AGC loop, so the very short term dynamic impedance at that node may be something considerably different from zero. But if you do power measurements with varying loads, it will appear that the impedance there is very close to zero. (Then you can put a 50 ohm resistor from

that node to a precision 50 ohm line, and have a very good 50 ohm source; you can put another 50 ohm resistor from that node to another line and have two matched sources, for testing other circuits...part of a vector network analyzer.)

Cheers,
Tom

Actually my short answers are short because they are to the point if I can find one in your ramblings.The point I made illustated an obvious fault and inconsistencey with your reasoning which you deflect with insults because you have no answers. I know what I had had no value to anyone else but since

you were makeing an iirelevant connection between tilt angle of a V antenna and polarization I thought it may give you some pause for thought. Obviously a wasted effort on my part

Jimmie

Jim Pennino, it was only a short time ago that you showed your
ignorance of electrical laws (gaussian) by calling it nonsense and
babling. Now you are attempting to concilidate your position of
ignorance, and doing quite well at it I might add. I suggest you
accept the same advice I gave Jimmie if you want to avoid being blown
away by electric laws once again.

Tom, I chose the word optimum for a reason, and I agree with you.

The design process does not find a drop dead maximum power in the way that loading a source with a variable impedance finds a maximum power. The rated power of an amplifier is a compromise, and dependent on the available voltage and current, required linearity / IMD, active device characteristics (eg saturation effects), dissipation limits (anode, control grid etc), harmonic output, efficiency to name just a few. To complicate crude experiments to determine maximum power output, the valve is usually operated close to saturation, so small load changed result in severly non-linear behavior. Further, apparent output impedance is affected by the regulation of the DC supply, which is many transmitters is better for short term current demands than sustained load.

For example, I have a Ameritron AL811H amplifier with 4 x 811A. The operating point for SSB telephony is different to AM due to anode dissipation limits. Some would suggest that when optimised for each of the SSB telephony and AM operating points (ie different anode load resistances) into a 50 ohm load, that the equivalent source impedance *must* be 50 ohms, and that it happens without specific design provisions.

No Jimmie, Richard Harrison gave a very clear starting point to my question which I might add was about an observation about dipoles. The "v" antenna was a subset of the discussion about the possibility of take of angle relative to the plane of antennas generally. None of the above refer to making a salad as you put it. I would point out however that the subject of TOA is a sutle question that relates to both instances but I will leave it up to you to determine that if you wish. On the subject of making a salad that was your statement not mine that you refer to as insulting.
Cool down for a while and then step back in

Hi Harold,

I've found out that it takes a lot of time to spar with Richard C.
When he gets ya he won't let go. He and I have somewhat different
backgrounds--he's an English major, while mine are math and physics.
That's probably why his definition of 'interference' disagrees with
mine.

As you've probable already determined, I maintain that modification of
an antenna pattern from that of a single dipole results from
interference between the fields radiated from more than one radiator,
and the pattern is determined by the relative phase between the
interfering fields. Kraus developed 'interferometers' to analyze the
field relationship between the fields radiated from the radiators in
his radio telescope. What more does one need to understand the effect
of interference? SWR on a transmission line is another example of
interference, that between the forward and reflected, is it not?
Thanks for permitting me the 'time'.

Wow, I didn't know you lived near San Francisco. Your pattern of life is certainly different to that of the Mid West. I suppose if you must live near your "friemds" then you must go where the action your looking for is at.
Hopefully you live at a long distance from schools and your computor is scanned regularly by the authorities.I had suspected from your postings that you were not "normal" as well as being uneducated. I am going to plonk your posts as I don't wish to be associated with you in any way especially that kind of talk. You make me shiver....

Richard, it's very uncommon, but on this issue I'm having a difficult
time following you. The only reason that I can conclude for my lack of
understanding is that our definition of 'interference' must be
divergent. So I'll just drop the discussion--OK?

The last sentence should read:

Essentially, the value calculated for a class B amplifier will be about
half the inverse of the slope of the constant grid voltage line.

> calling the generator impedance.

It would appear that you are confusing the possible complexities
of a class C power amplifier with the simplicity of the generator
in the experiment I proposed. A 2 Amp current source
in parallel with a 450 Ohm resistor does not, as far as I can
tell, have a 'non-dissipative source resistance'. It has a
dissipating source resistor. This is not a particularly efficient
implementation, but is certainly a possible one. Now that I
have clarified that there is a dissipating source resistor will
this allow you to use superposition to solve the problem?

Just for your convenience, a reminder of the problem:
- generator with 450 Ohm source resistance drives
- a line with 450 Ohm characteristic impedance
- terminated by a 75 Ohm load
- the generator is set such that it would output
450 Volts into a 450 Ohm load

Question:
- Will there be ghosts?
If the answer is yes...
- What is the magnitude of the first re-reflection?
Ancillary question:
- What 'forward power' will a directional wattmeter in the
450 Ohm line indicate?
- What 'reverse power' will a directional wattmeter in the
450 Ohm line indicate?

If necessary for answering the question:
- The line can be assumed to be 31 wavelengths long.
- The generator can be assumed to be a 2 Amp current source
in parallel with a 450 Ohm resistor.

...Keith

> 73, Cecil http://www.w5dxp.com

I didn't catch this first time round, but better late then never.

As you say, adding 1 wavelength of 75 Ohm line will not change
the steady state.

So the condition on the right side of the inserted 75 Ohm line
section will be reproduced on the left side of the line section.

This means that reflecting back into the generator from the
left end of the 75 Ohm line will be the same Pref2 = 229.6 W
that exists on the right side of the 75 Ohm line section.

If you doubt, do the same energy analysis for the left end of
the line that you did for the right end. The generator is
putting 450 W forward into the connection to the 75 Ohm line,
229.6 W is being reflected and 220.4 W is entering the 75 Ohm
line. All is in balance at the connection at the left end
as it is at the right end. But 229.6 W are going back into
the generator. Where do these Watts go?

Using your analytical approach it may help if you put a one
wavelength section of 450 Ohm line between the generator
and the 75 Ohm line section previously inserted. This will
not change the steady state result but may make it easier
to visualize the reflected 229.6 W.

Owen
I agree. Amateurs and probably some professionals place to much weight
on total antenna gain as opposed to maximum gain of the required
polarity and frankly polarity is always of primary importance for all
antennas. This rationality also include the attainment of less
required compromises with other factors when dealing with bandwidth
(per the above comments referncing matching.) Compromises with respect
to the design of yagi antennas is extensively described in most ARRL
publications and are best avoided.

3520. a tuned counterpoise system question

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-02 04:43:11 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <upKdnfW_yv-VF43bnZ2dnUVZ_hudnZ2d@comcast.com>
Source record: 43692

All,

I am interested in building a tuned counterpoise system. The antenna is a screwdriver and the frequency of interest is 3970 kc. Reg's c_poise program predicts a reasonable set of parameters, a 10 foot 'wire tube', one meter up, and a coil in the range of 50 uH. The program predicts a 'ground' in the range of 5 Ohms.

How oversimplified is this?

The current ground measures over 40 Ohms and the system is just over 5% efficient. To go from a ground of 40 Ohms to one of 5 Ohms gives the potential of a system efficiency approaching 50%. An 8 to 1 increase in efficiency could yield a 9 db improvement. This is worth some serious experimentation.

Thanks for you thoughts and analysis in advance - Dan

>pattern results from interference between two coherent fields?

Hi Walt,

Of course a null, or a peak, or any point in between results in the interference (the combination of energy phases as power from separate sources, or separate waves) found only in a load. I recall having posted comments specifically to the issue of phase combination several many times in as many days. I will do it several times more here:

That same point in space without that load has absolutely no effect on any energies that passes through it. Energies do not mix (combine) in linear space; thus one energy can have no effect on other energies. Any single energy is unperturbed by any other energies without that load to offer a point of summation (the point of interference). That unloaded point in space cannot support reflections or force any change on any energy.

Interference is not the cessation of energy flow; it is not an impediment to energy flow; it is not an redirection of energy flow; it is not the amplification of energy flow; it is merely the passive observation at a point of the summation in a load of all contributions of energy flow. Further, the load may compound the redistribution of energy flows (AKA directors or reflectors) becoming, as it were, a new and separate source for a yet another remote load to combine new phase relationships into a new null/peak/what-have-you. Remove the load, and those products disappear.

Interference follows the load. Interference is caused by source relationships developed at the load. Move ANY of these actors, and the entire map of responsivity changes. All antenna graphical lobe descriptions demonstrate this.

Message-ID: <1175497378.760848.33570@l77g2000hsb.googlegroups.com>
Source record: 43694

I'm fairly new here so if this post is not appropriate for this group, direct me elsewhere.

I am using the EZNEC demo to analyze an Off Center Fed sloper I am using on 75m. The antenna is being fed with 85 feet of 450 ohm ladder line which runs all the way to my operating location. At 3.9405 Mhz, EZNEC shows an impedance of 28.11 -j102.2 at the transmission line input (Alt Z0 of 450 ohms). My MFJ auto tuner (L-Network) is actually matching the sloper at a 1.1 SWR with an inductor value of 5.34 uH and a capacitor value of 605 pf. The capacitor is shunted on the transmitter side of the inductor.

I am using a formula I found in the L-Network section of Chapter 25 of the ARRL Antenna Book to take the MFJ tuner values above and calculate the impedance the tuner is matching. There are a couple of statements in this section of the Antenna Book which lead me to believe that L-Networks are used for matching purely resistive loads. It also states that loads containing "reactance" can be accounted for in the L-Network inductor or capacitor values. Do I need to eliminate the portion of the tuner inductor value being used to bring the system to resonance before I calculate the impedance transform? If so is there a way to do this or is my whole approach here off base?

Thanks for any replies. Interesting stuff.

Your values, if they are correct, suggest that Z is more like 18-j211
(depending on the Q of the coil).

Your transmission line may not be the 450 ohms that you think, and is a
likely contribution to error.

EZNEC probably models lossless transmission lines, and probably assumes
Zo is resistive. Combined with probable error in Zo, the input impedance
of the line may be different to model. Further, the feedpoint impedance
may be different to model, modelling an off centre fed antenna is
problematic.

Is that a base load? Seems to be using a 50 uH coil.. I'd be thinking
70-80 uH
for a short center load...?

> Thanks for you thoughts and analysis in advance - Dan

I'm just wondering why you want to use this type of antenna. Seems
like a
lot of work involved to get semi decent performance vs even a simple
dipole.
IE: why only a 10 ft whip? Is this for some type of portable use?
To get a low ground loss you will need quite a few radials when near
the ground, and using the short antenna makes things even more
critical.
If I had a mobile whip, I'd just as soon mount it on a car, and run
coax to it,
vs other options.
If this was at the house, I'd try to use a taller vertical, use top
loading
wires, etc.
But most of my 75m stuff is fairly local NVIS yik yak, so I'd just as
soon be
on a dipole.
You say the mount is three feet up... Might as well be on the ground
as far as the number of radials needed. They can be resonant, and
there
will be a slight advantage over non resonant radials laying on the
ground,

but nothing earthshaking. Don't expect high efficiency with 2-4
radials
strung 3 ft in the air. You'll need 30-60 just to get in the medium
performance
mode, and you would still be in the mud vs the usual dipole..

Dunno...I may be confused... But I don't see it..If I was going to get
on
75m, I'd stick up a coax fed dipole and be done with it. It would
smoke
that short vertical running over most any counterpoise you might cook
up.
I can live with a short vertical when mobile because I have no choice.
But otherwise, I can think of better antennas for that band. But I
don't
know if you work NVIS or DX.. Even with DX, a vertical will need to
be
fairly decent to compete with an efficient dipole at even 25-35-45 ft
up,
which is pretty low height in wavelength for 75 meters. I work DX on
75m
with 100w no problem at all using a coax fed dipole at about 40 ft.
This is not to say I don't like verticals.. I do. But I would try to
run a bit
more robust version than a screwdriver unless actually mobile..
IE: a simple inv L or T made of wire "60-65 ft" thrown over a tree
will
usually outdo the short whip. I like the "T" better for a pure
vertical
pattern with little horizontal componant.
But I'm much more likely to use a T vertical on 160m than I am 80..
I'm almost always on the dipoles on 80m. Well, actually a turnstile
at the moment.. Crossed dipoles..

Nothing too sophisticated, I plugged them into a Smith chart program and played with the load until it matched to approx 50+j0. It could be done with a hand calculator nearly as quickly.

BTW, you might find the line loss calculator at http://www.vk1od.net/tl/tllc.php helpful, you can specify the Z looking into the line, or at the load end of the line, and it will calculate the other for you (using a lossy line model).

>are radiating equal EM energy? Are you still denying that interference is not the cause of the modification of
>the resultant fields? So I repeat the question--where is the load in this case?

Hi Walt,

The load is anywhere you place it, obviously. We can even abstract
one radiator of these two radiators being a load for the other - and
through symmetry, the other way around. They obviously interefere
with each other. As I've offered, remove (or simply move) either and
the entire picture changes. If you want to add yet another, remote
load, that is fine. There is no limit to where it can reside. There
is no limit in the number of loads either. All loads reveal
interference, however, if you remove them, obviously there is no
interference.

Fields do not act one upon the other in linear space. The addition of
a load may present a new source of radiation. In that case, the new
mapping of wave action follows the load. This is demonstrated in
every yagi. Remove the load (or yagi element) and the specific
mapping changes, following the load.

Hi Walt,

Zero radiation results from a particularly small in relation to
wavelength separation of wires. In a very close proximity, all loads
see the same phase balance (0), hence the combination of these issues
of distance with regard to wavelength render a null in any load remote
from the line you have described.

>Also, consider standing waves on on a line, resulting from the superposition of the
forward and reflected
>waves, where the maximum amplitude results from constructive interference and the minimum
amplitude results
>from destructive interference. Are you denying the existence of interference in this case?

In a lossless line, you can't tell the difference. In a lossy line,
you have found a load. As any lossy line generally presents the same
loss on a per-length basis, it is obvious that phase combines to
create loss in only certain positions with regard to distance and
wavelength. Mapping will follow the load.

Barring either of these cases, you have to insert a load into the line
to force the interference. Sure, you can anticipate it
mathematically. And certainly it will be borne out in practice with
lossy line melting or arcing at cardinal points. Without that loss -
who cares? Nothing happened or will happen and the waves will never
interact to give a new product as (I imagine we have agreed) this is
linear space.

The operation of TR/ATR tubes in transmission line systems works with
this to force interference to steer radiation. Remove the tubes and
the action ceases. The fields in an identical transmission line
environment cannot do it themselves without that load present. This
is classic RADAR systems topology.

Imagine what this would be like with the "Magic T?"

Thanks,

The input to Reg's program is:
F 4 MHz
H 1 M
L 3.3 M
D 25 mm
A 98
B 70
R .7
G 40

This yields 3.2 Ohms input impedance. The coil can be made from PVC and
12 gage wire, the rod, wire, can be 1 inch copper tubing.

- Dan

OK, genius, what is POLARITY and how did we manage to ignore it over the
century plus of fiddling with antennas?
I promise to always use PLUS or POSITIVE polarity, never to engage any
NEGATIVE, which would be detrimental to Gaussian jambalaya.

Good day!

In some of the articles that I'm reading, I keep seeing references to a DC injector use in RF ports. I really don't know what this means and what the DC injectors are used for. The only think that I can think of is for some DC voltage control for a voltage controlled oscillator (VCO).

Thank you!

Wim
Earlier I explained that the gaussian law can be expanded to provide a link to a radiator. The mathematics has been provenon this newsgroup. Unfortunately only one person accepted that proof. Using this new aproach,thesis or what have you provided for the generation of arrays where all radiator were resonant which provides specific advantages. It also provides for multiple arrangements of elements for maximum gain by virtue of the condition that equilibrium must be maintained in the enclosed volume of a standard Gaussian field which means that more than one arrangement of a given number of radiating elements can be arrived at for maximum gain.
Thus not only was the theory proved by mathematics in accordance with known laws it has also been overchecked by the use of the equilibrium condition which was imposed as well as all being confirmed by accepted computor programs. Since all new theorem are immediately rejected by the vast majority of this group but with one exception from down under you surely can understand the futility of convincing people until they see it written in a book because of their lack of individual thought. One thing I have proved to my satisfaction that many who perceived themselves as experts have shown quite clearly that they have over estimated their abilities.
When my work is published it will not only be seen that many were unable to think on the basis of there own knoweledge but also their knowledge of Electrical laws were flawed. That was my intention to prove when I introduced extension of known laws on this newsgroup plus the exposure to all of the residing pseudo experts. Time will tell that I have suceeded
in my mission

Hi Dan,

By Reggie's own warning, it will suffer for being so close in
proximity to earth. He does, however, offer the advice (probably for
any construction) to allow enough surplus material to permit tuning.

I should point out that with any tool, its utility is comparing its
forecast with your results. If you do enough constructions against
that tool, and you look at the range of forecasts and compare to
results, you will build your own correction factors that will make
future constructions easier to accomplish.

This lesson was more what Reggie was trying to teach. Those who use
his tools without examination would be eaten alive by the Sewer Rats
of Rio.

I am one who missed Art`s explanation. I am curious as Gauss and antennas have not been directly related in my mind.

Wikipedia says:
"The total of electric flux out of a closed surface is equal to the charge divided by the permittivity."

J.C. Maxwell may have found Gauss useful, but why do I need him in amateur antenna wotk?

Best regards, Richard Harrison, KB5WZI

If you add time to both sides of the Gaussian law you have the
connection
which is more specific than that stated in Maxwell laws .Specific
means the shape of the radiating cluster in question upto and
including resulting radiation desirables. A quick search on "Gaussian"
will bring you upto date
All have been extensively stated.

Besides the use Philo mentioned, such beasts are also used with network analyzers to inject a DC voltage (or current) to bias a device that's being tested. For example, if you want to use a network analyzer to look at the impedance of a varicap diode, or just to characterize the capacitance versus reverse voltage of an ordinary diode, you need a way to put a controlled DC bias on the diode. They typically consist of an RF choke to feed the DC onto the output connector, and a blocking capacitor to keep the RF input from shorting out the DC.

Cheers,
Tom

I am looking at buying a used Cushcraft R8 antenna that includes the "MN8 matching network." I can't find anything on the net about the matching network.

1. When I inspect the antenna, what specific things should I inspect for?
2. What good is the MN8 matching network. (I've got a Yaesu FT-990 if that makes a difference.)
3. Anything good to say about this antenna?

Thanks all!

> the dynamic source resistance and the load resistance are the same.

Does that take into account the step-down transformation?
The "source load" that results in the "source load line",
is not the physical load in the system. It is the physical
load in the system transformed by the transmission
line, the filters, the tank circuits, and the transformers.
In short, it is the transformed load seen directly
by the source - at the source.

For instance, a source may have a dynamic source
resistance of 1000 ohms. A 20:1 tank circuit
transformation takes it to 50 ohms. The load line
for that amp has a slope of 1000, not 50.

Hello Walt,

Please know that all of my comments are offered with all due respect, and there is a lot of respect due, and sincerely felt. However, though the numbers work out as one would expect given the effects that are observed, cause can only be attributed to phenomenon which is observed in nature. Electromagnetic waves can reflect only from real media. Though I admire the procedure you have devised for describing the complex effects of these reflections, the attempts to extend those ideas to describe real (not virtual) physical phenomena are unsupported from a scientific standpoint. Inference is insufficient proof.

Specifically: The nature of reflective surfaces does not depend on whether or not steady state has been reached. Their reflectivity does not change as a function voltage. Their nature does not depend on things which lie at the other end of the transmission line - even though the overall performance of the system certainly does. The nature of reflective surfaces does not depend on how many times the wave has bounced back and forth since the signal was initiated. These things are implied by your claim, unfortunately.

In the case of optical media, reflectivity is determined by the relative indices of refraction of the optical media comprising the reflective surface. Neither the indices, nor their ratio changes in response to illumination. Likewise, the reflective nature of impedance discontinuities on a transmission line depend entirely on physical constants analogous to optical indices of refraction. These attributes do not tend to change when illuminated by RF.

I thought we had covered this ground back a couple of years ago when the topic of reflections from virtual shorts and opens came up on this newsgroup. At that time it became clear that certain of the predictions made under the model did not match well with reality. For example, the virtual short circuit which can appear at the entrance to a stub on a transmission line would, according to the model, prevent the very currents necessary for creating the virtual condition from entering the stub in the first place. Reflections can occur only at physical discontinuities, not at a voltage to current ratio.

I was encouraged by the work we did on your transmission line impedance matching transformer diagram. In that, it seemed we agreed that the reflective coefficients were constant, were determined by the characteristic impedance's of the transmission lines, and that steady state was in fact comprised of the summation of a long series of multiple partial reflections. And, it correlates exactly with the descriptions and drawings of the analogous optical phenomena in the physics texts.

I really admire your work, Walt, but I feel this one point is clearly inconsistent with nature. Let me hasten to add that I see nothing at all wrong with making calculations based on this model. Its utility and beauty lies in its accuracy at the macroscopic level. I also think that your treatise on interference as it applies to the

reflections found in RF systems is well done. The error I find is in your notion of interference as a cause of reflection, which I assume is extrapolated from your notion that virtual shorts and opens cause reflections, and, that real reflective coefficients may be calculated from virtual impedance's.

Best Regards,

Jim Kelley

Yep, I didn't say that very well. Let me try again.
EM wave energy in a transmission line can only change
directions at a physical impedance discontinuity.

I am ignorant of any technical words (if they exist)
for what I am about to describe so bear with me.

Interference can have totally different outcomes so I
have to ask, are there different kinds of interference?

For instance, the interference between the forward wave
and reflected wave that causes standing waves has no
effect on either the forward wave or the reflected wave.
In an unchanging Z0 environment, the forward wave and
reflected wave pass like ships in the night. For want
of a better term, I will call this type of interference
"temporary interference".

The other type of interference occurs when reflections
are eliminated at a Z0-match or a non-reflective thin-
film. This is *wave cancellation* between two coherent
waves of equal magnitude and opposite phase traveling
in the same path in the direction. For want of a better
term, I will call that type of interference "permanent
interference" since the two waves are canceled and
disappear. Their energy components are redistributed.

Are there any technical words to differentiate between
the two types of interference?

Close enough for a laser beam. The unit of irradiance is
watts/unit-area. The square of the radius of the laser
beam times pi can be considered to be the unit area. Thus
the unit area is implied and fixed but not specified.
The same is true for a coaxial transmission line. Given the
line, the unit area term can be dropped without error.

Win,

your explanation is very good and convincing. I believe that most of us would read with interest some further remarks on what happens in the case of a shorted element (e.g. a director or a reflector), instead of the driven element.

In those cases all received energy must be re-radiated, but more details on that mechanism would be welcome.

Cecil,

The two previous paragraphs that you have omitted in your quote provide the context for the paragraphs that you did quote. The context is in the anode circuit of the PA being discussed.

> The "source load" that results in the "source load line",

I don't really understand the concepts of a "source load" or "source load line". Perhaps your meaning is the load in the anode circuit of the PA, I will read on with that interpretation.

> is not the physical load in the system. It is the physical

> transformation takes it to 50 ohms. The load line
> for that amp has a slope of 1000, not 50.

I am not comparing apples with oranges, not comparing impedances on different sides of the pi network.

To expand the first example with the details:
-if Ql is 10 and Ra is 1400 ohms, a 1% decrease in the extenal 50 ohm load results in a 0.26% decrease in the anode load impedance

Rl=50, |Za|=1400.0;
Rl=49.5, |Za|=1396.4, a 0.26% decrease in |Za| for a 1% decrease in Rl.

You cannot think of a PI coupler (and the original post was discussing a PI coupler) in this application as an idealised symmetric n:1 transformer, whilst this coupler has an apparent ratio of 28:1 (1400/50), incremental impedance changes are in a quite different ratio.

A PI network is not in the general case symmetric, your example of a 20:1 "tank" circuit (and I would argue that "tank" is usually used to mean a parallel tuned anode circuit, typically link coupled) is not symmetric and the point of my post was to say that Zin/Zout is not a straight line, and general analyses based on a fixed ratio are likely to be flawed.

Since ZERO reflected energy exists anywhere on the
75 ohm line, your assertion doesn't make any sense.

Now consider that the 75 ohm line can be one foot
long and everything is the same as the 1WL of 75
ohm line (except the delays).

If adding one foot of 75 ohm line inside the source
completely eliminates reflections, then the source
impedance doesn't matter at all because all it is
delivering is a voltage.

I don't understand "a 50 ohm load resistor driving a 50 ohm load".

The transformation issue pertains to the PI coupler, you cannot treat a
PI coupler in the general case as an idealised symmetric n:1 transformer.
It certainly isn't in a typical single ended RF linear amplifier.

The impinging field induces a current on the element. The current produces a field which radiates. An AC current flowing on a conductor creates a field regardless of how that current is produced. It doesn't matter whether the current is due to conduction from a source, by induction from a field, or any combination of the two -- the field resulting from the current is exactly the same. Yagis and other "parasitic" arrays depend entirely on this phenomenon for their operation.

(Yes, I was well aware that you were taking issue with the usually assumed use of "optimal." Sorry if my previous posting might have suggested you agreed with it.)

More on how things reflect through a pi network: consider a pi network at 5MHz designed to present a 1400 ohm load to the plates of an amplifier, given a 50 ohm output load. One such network is 215pF at the plates (including plate capacitance), 5.397uH, and 950pF at the output. If the plate resistance--the net resistance you see looking back into the plates, excluding the capacitance at that node (since it's included in the pi network), is 2000 ohms, the impedance seen looking back into the pi output terminals is 50+j18: the resistive change at one end resulted in an almost purely reactive change at the other. If Rplate = 4000 ohms, the impedance looking back into the pi output is about 36+j45. Rplate = 6000 ohms ---> 26+j53.

At least in theory, it's possible to use a 1/4 wave transmission line to match the 50 ohm load so it presents 1400 ohms to the plates: a 264.57 ohm line will do the trick. But then plate resistances of 2000, 4000 and 6000 ohms reflect pure source resistances of 35, 17.5 and 11-2/3 ohms, respectively.

You can make a lower Q matching network that still has good attenuation of harmonics by using more L-C sections. If you simply add an inductor to the output of a pi network, you can again match a 50 ohm load so it presents 1400 ohms to the plates, by using (still at 5MHz) 3.1uH to the output, 258pF shunt to ground, 16.74uH in series to the plates, and net 50pF from plates to ground. Now plate resistances of 2000, 4000 and 6000 ohms reflect the following source impedances at the output which is designed to be loaded with 50 ohms: 43.32+j15.33, 26.19+j31.88 and 18.16+j35.73.

Adding another L-C "L" section to the output (3 inductors in series, three capacitors shunt to ground) you can end up with a network that yields, with the same 1400 ohm load to the plates with a 50 ohm output load, and the same 2000, 4000 and 6000 ohm plate resistances, 65.18+j13.81, 85.88+j62.5 and 82.11+j96.58 ohms source impedance.

In summary, the output network can -- does -- have a big effect on exactly what a given effective plate resistance will reflect to the output port. There's a huge variety of possible output matching networks, and an infinite set of part values, that will yield the "proper" plate (or collector or drain...) load, for good power output with reasonable efficiency and reasonably low distortion. There usually isn't much reason to CARE what the source impedance is, looking back into the output port, but if you do care, make sure that you understand what your output network is doing to transform the plate impedance as seen at the output port.

Cheers,
Tom

I'm afraid that your model isn't adequate for the antenna. In an off center fed antenna, there will be considerable common mode feedline current -- in other words, the currents on the two feedline conductors won't be equal and opposite, so the feedline will radiate and is an integral part of the antenna. A model has to include the feedline (as two wires, not as a transmission line model which doesn't radiate) in the correct orientation relative to the antenna, plus the entire path to ground from the transmitter. This path is seldom known. A simpler model which ignores the very significant contribution of the radiating feedline won't give meaningful results.

This is not at all true. I'm guessing you're misinterpreting what's written there. If not, and it really says that, it's an error which should be corrected.

L network values for matching are best done by beginning with the required impedances at both ports, then directly calculating the necessary component values. A number of programs are available to do this calculation for you, or if you prefer, it can be done quite easily graphically with a Smith chart.

A class A RF amplifier can certainly be fed its DC through an RF
choke, just as is done with other classes. There's no need to limit
the discussion to class A.

If you put a resistance Rshunt in parallel with the plates (or
collectors or drains), at the plates, such that the plate resistance,
Rplate, in parallel with Rshunt equals the load presented by the
output network to the plate circuit, then the source impedance seen at
the output terminals will be the same as the load impedance. That may
be a little confusing...let me put it differently. Consider an output
passive, linear network with two ports, the Plate port and the Load
port. When the Load port is loaded with Zload, the rated load
impedance, the Plate port presents an impedance to the plates, call it
Zpnetwork. If you put an additional load at the plates such that the
Plate port of the network "sees" an impedance equal to Zpnetwork
looking toward the plates, then when the network is connected to the
plates and that additional load, you will "see" a source impedance
equal to the conjugate of Zload looking back into the network's Load

port.

For example, let's say that we have a 6000 ohm plate resistance, and a 4000 ohm resistor we put in parallel with the plates (put it shunt across the plate DC feed RF choke which is considered to be essentially infinite impedance). The net resistance looking into that is 2400 ohms. Assume a load of 50+j50 ohms. Assume an output network that, when loaded with 50+j50 ohms, transforms that to 2400 ohms, resistive. Then the impedance looking back into the output port of the output network will be 50-j50 ohms. It doesn't matter if it's a pi network, a filter, or a 81.52 degree long piece of 342.73 ohm "lossless" transmission line.

But if the goal is to deliver as much clean RF power to the external load as you can, why would you put an RF-dissipating resistor into your amplifier?

Cheers,
Tom

I missed the relevance of the class A amplifier.

The example that I worked up in the original post was for a design anode load of 1400 ohms, using a practical PI coupler to a 50 ohm external load. It is theoretical treatment of the kind of coupler circuit that you would expect to be in the transmitter for which Walt reported his detailed measurements.

Hi Jim,

Thanks for taking the time to write such an insightful response--I
was
expecting it.

At the moment I'm in a hotel in Jacksonville, going through pre-op for
spinal
surgery. I'll be home Wednesday, and that will be the earliest I'll
have the
opportunity to review your comments. So I'll get back with you after
having the
time to review it.

Thanks again, Jim,

You haven't moved beyond that "first amplifier that is taught in EE 202"?

If your goal is to deliver as much clean RF power to the external load as you can, why would you put an RF-dissipating resistor into your amplifier?

Cheers,
Tom

> amplifier?

My goal is not to deliver as much power as possible.
My goal is to understand the nature of the source
starting with the simplest one.

Accordingly, the fraction of energy that changes direction at a
physical discontinuity is dictated by the physical constants of the
physical discontinuity; index of refraction in the case of optics;
impedance in the case of transmission lines.

> definitely pursue.

You raise an interesting question. What are the design tradeoffs
that drive choosing between a ten cent resistor and a circulator?
I suspect it relates mostly to the powers involved. The ten cent
resistor seems to see application in signal generators where the
extra power it dissipates is not of concern and it really is a
ten cent resistor. In high power applications, it definitely
would not be a ten cent resistor and having an amplifier which
can provide twice the normally required output voltage would be
far from efficient. It is perhaps here that a circulator finds
application driven by simple engineering cost-benefit tradeoffs.

> information to solve the problem. Again, please
> furnish a math model of a real world source.

So why don't you prove my contention that the impedance
encountered by the reflected wave is 450 Ohms incorrect.

Here is how. Using my 450 Ohm value for the impedance
compute the reflection coefficient at the generator
using RC = (Z2-Z1)/(Z2_Z1). Using the various equations
for Vthrough, Vreflected, Ithrough and Ireflected, along
with superposition compute the various currents and
voltages within the system.

Then using Kirchoff's voltage and current laws, validate
all the nodal voltages and loop currents. If 450 Ohms is
not the appropriate impedance, then the validity check
will fail.

The beauty of this approach is that you do not need to know what the actual value is, you merely need to prove that it is not 450 Ohms.

I await the analysis.

Jim Kelley wrote:
"The error I find is in your notation that virtual shorts and opens cause reflections, and that real reflection coefficients may be calculated from virtual impedances."

Impedance is a voltage to current ratio. A low impedance allows much current from a low impressed voltage. A high impedance only allows a low current from a high impressed voltage.

A transmission line with a mismatched load, has a reverse or reflected wave traveling back from the load in addition to the incident wave traveling toward and impressed on the load. Both waves, incident and reflected, have the same voltage to current ratio. It equals the Zo of the line and is enforced by the construction of the assumed uniform line.

Superposition of the forward or incident wave and the reverse or reflected wave produces periodic variations in the combined volts and amps along the line. The rms values of the constituent volts and amps are likely very steady. It`s their combination which varies.

High voltage points are high impedance points. Low voltage points are low impedance points.

Severity of voltage and impedance variations along the line depends on how different the load impedance is from Zo.

A short or an open on the line can produce segments analogous with series and parallel resonant LC circuits (which behave as shorts and opens with respect to impedance for example).

Input impedance of an open circuited line of length less than a quarter wavelength is capacitive. Input impedance of an open line of length greater than a quarter wavelength but less than a half wavelength is inductive.

An open-circuited quarter wavelength of line is practically a short circuit at its input.

A quarter wavelength back from a line short, its impedance is is an open circuit, and as above, a quarter wavelength back from an open circuit, the line impedance is a short circuit.

At a line short circuit, incident and reflected current phasors are in-phase while the incident and reflected voltage phasors are out-of-phase.

A quarter wave back from the short, the incident and reflected current phasors are out-of-phase while the the incident and reflected voltage phasors are in-phase.

A quarter wave back from a hard short on a good line, the reflected voltage is equal to and of the same phase as the incident voltage. Therefore there is no potential difference between the incident and reflected voltages at this point and the current is zero. This is analogous to connecting identical battery cells in parallel. No current flows between them. The same can be said of connecting correctly phased identical transformer windings in parallel.

High voltage and almost zero net current means the impedance is nearly infinite. This is similar to a good parallel resonant circuit. It is almost an open circuit. Quarter wave shorted stubs have been used as "metal insulators" for line support and other purposes.

I have no problem with "virtual shorts and opens". We so called them and used them in school when I was there over a half century ago.

Examine RADAR TR and anti-TR circuits for examples of virtual shorts and opens which automatically route the energy to the right places and keep it out of the wrong places.

Best regards. Richard Harrison, KB5WZI

Please try again after adding 1 more wavelength of 450
Ohm line between the generator and the 75 Ohm line you
added. Kindly explain where the 'reflected power' on
this new section of 450 Ohm line goes.

> Now consider that the 75 ohm line can be one foot
> long and everything is the same as the 1WL of 75
> ohm line (except the delays).

This would be quite incorrect. The impedance presented to
the generator is quite different. Do recall that by design
the generator has a 450 Ohm output impedance so there is
a physical discontinuity at the connection to the 75 Ohm
line. In this case the 75 Ohm line is acting as an impedance
transformer and its length is very relevent. Make it a
multiple half wavelength and the transformation is unity.
I had assumed that this was why in your first analysis
you chose to add one wavelength of line and state that
this would not alter the steady state response, to which,
of course, I agree, though it quite alters the transient
response.

Are you sure? In other threads you consistently refuse
to analyse the simplest of sources on the basis (as far
as I can tell) that it is not the 'real world'.

In light of your new approach, which I wholeheartedly
endorse, perhaps you will reconsider your response in the
other threads and try to "understand the nature of the
source starting with the simplest one".

When you think of interference as being the instantaneous sum of waves
at a given position and time, then there is really only one kind of
interference to be had - though there are a variety of results which
can be obtained from it. It is useful to bear in mind that fields,
voltages, and currents are what give physical form to the waves in
transmission lines. Whether in a transmission line, or free space it
is the fields which interfere - not power, or energy.

All,

I have an 8418a with a liner/phase display and an 8418a with a polar display. Does anyone know how to connect the 8418a to the 8407a.

The 8418a has three inputs, amplitude, phase, and reference.

The 8407 has two outputs, phase+amplitude and reference.

The reference would connect to reference.

Is it as simple as connecting the 8407a phase+amplitude to both 8418a phase and amplitude?

If your goal "is to understand the nature of the source starting with the simplest one," why would you add resistors you don't need and make it more complicated than the simplest one? What if "the simplest one" turns out to lead you into believing generalities that are not true, when considering a more general one will avoid that?

My goal, in the context of Owen's basenote, remains to deliver as much clean RF power to the external load as I can. Unnecessary resistors need not apply. Matching networks better pass muster with respect to their performance not only at fundamental frequencies, but also at others, especially at harmonics. Not all the networks I've posted about in this thread do pass muster, but are enlightening with respect to Owen's observations, I believe. Simplest doesn't remain interesting for very long.

FWIW, I don't see anything in Owen's postings in this thread that _precludes_ a source impedance that's equal to some particular load impedance, or to its conjugate. Rather, I see a suggestion that the source impedance does not necessarily have to be equal to any particular value, and in the general case does not have to be equal to the conjugate of the design load impedance. With that I agree. I've seen a great many examples of it. I gave a few of them earlier. I've also worked on the design of broadband RF amplifiers which are designed specifically to be 50 ohm resistive sources, through the use of feedback to set that impedance. You don't need brute-force resistors to do it; most of the time, you don't need to do it anyway, but in the case of instruments used for measurement, it can be

important. In the case of video amplifiers where ghost-causing reflections are to be kept to a minimum, it can be important. In the case of a ham narrow-band SSB, CW, FSK, FM or AM transmitter, I question whether the source impedance is ever important, or is ever accurately known. Perhaps someone can convince me otherwise, though a well-thought-out, well-presented example.

Cheers,
Tom

Tom, I suggest that amplifiers with a specific equivalent source impedance to low tolerance don't happen by accident or by magic of a PI coupler, they require design measures that are not usually applied to amplifiers for SSB telephony.

The assertions here that "conjugate matching" occurs naturally as a by-product of peaking the PA is not consistent with the realities of design of amplifiers with specific equivalent source impedance.

The amplifier configuration I used as an example was a single ended class B valve RF linear with PI coupler for SSB telephony for comparison with Walt's test. A push pull class B bipolar transistor amplifier with broadband transformer coupling and high pass filter will behave differently, and some of those designs include negative feedback which reduces the equivalent source impedance. (I am not talking ALC here, ALC is in the form of dynamic power control rather than reducing the equivalent source impedance, though you could be fooled by some steady state tests into thinking it has reduced the equivalent source impedance.)

Absolutely. The amplifier designs I referred to took some work to get
"right."
>
> The assertions here that "conjugate matching" occurs naturally as a by-

If I understand you correctly, I again fully agree. The design goals
of ham, and for that matter most commercial, RF power amplifiers put
things like decent efficiency, low distortion and stable operation
well ahead of any consideration to design to a particular output port
source impedance. Rarely is that ever even considered, since it
doesn't matter.

I would point out that negative feedback does not necessarily reduce the output impedance. Voltage-derived negative feedback does, but current-derived negative feedback increases output impedance. If you analyze the difference between a grounded-cathode and a grounded-grid amplifier from the point of view of negative feedback, you will see that the grounded grid amplifier has higher source impedance, viewed at the plates. The driver source impedance in the cathode circuit effectively monitors the cathode current (which is very nearly equal to the plate current), and generates negative feedback to the grid-cathode voltage as a result. Adding a small cathode resistance to a grounded-cathode amplifier will have a similar effect; the effect on the impedance seen at the plates is much greater than the resistance placed in the cathode circuit. What you see through a pi or other coupling network depends on that network, as shown in the examples I posted earlier today, and generally will be much different than what happens at the plates.

Actually, the comparison of a grounded-cathode and a grounded-grid amplifier is a good illustration of how the plate source impedance and the optimal load impedance are unrelated. The change between those two types, for a given tube and given plate voltage, has a minor effect on optimal load impedance, and a major effect on plate source impedance.

Cheers,
Tom

Tom,

A good point!

I am playing around with a model of 4 x 811A in GG followed by a PI coupler into a nominal 50 ohm load to explore the small delta dynamic source resistance, and the common cathode configuration would be an interesting contrast. The interesting thing in modelling the GG triode class B config is that the changing driver load as Ia changes (ie the feedback) will vary in effect depending on the equivalent source impedance of the driver. Again another variable that mitigates against the accidental "conjugate match".

Yes, and with the corollary that you can never extract more than half of
the power/energy transported by an EM wave. That maximum (available
power) is given by Voc^2/(4 * Ra) where Voc and Ra are the open circuit
voltage magnitude and real part of the extractor (receive antenna)
impedance, respectively, measured at the antenna terminals at the
frequency of interest. The remaining energy is scattered (reradiated)
from the antenna. Sincerely, and 73s from N4GGO,

Source record: 43758

Hi,

I am wondering if anyone has data for a directional gain antenna (DGA). What I would need are the gains and the phase of the antenna as a function of (phi,theta). I am working with a group that has such an antenna, but I think that their work is not very good. I am not looking for anything fancy or even that good in terms of performance: I am doing some performance analysis using beamforming algorithms for GPS signal acquisition, and I want to incorporate DGA into my analysis and get some basic results as to how much the DGA improves performance. (Of course, any work I do, I would cite the use of your data).

You can reply either on the ng or to my e-mail address.

Thank you very much,

Matt Brenneman

Hi Richard,

If I gave the impression that I have a problem with virtual, or
effective impedances then I apollogize. I tried to make it clear that
the only problem is in improperly attributing cause and effect. While
I am not familiar with RADAR TR or anti-TR, I am quite sure that it is
subject to the same physical laws as any other technology.
Electromagnetic waves reflect only from real physical boundaries. JC
Maxwell took great care to describe exactly how that works. If you
feel that RADAR is somehow exempt from these physical laws, then this
might be an opportunity for us both to review our understanding of the
technology.

Best Regards,
Jim AC6XG

No. It is just two power sources using the same conductor. That is why there are capacitors at each end of the conductor. They permit the rf/ac signal to pass but block the dc from passing. The satellite tv systems use this to tune the block down converters out at the dish antenna.

Well not quite, Block DownConverters are not "Tuned". They take a
Fixed Bandwidth from the Input Frequency, and DownConvert it to
an equal Fixed Bandwidth at a lower IF Frequency. Back in the LONG
Past era, there were First Generation SAT Receivers that did have
the Frequency Selecting Mixer out at the dish, and used an IF of 70Mhz
to bring a Single Channel of Wideband FM Tv to the DeModulator in
the SetTop Box. This system was universally designed out of the
Consumer SAT systems due to Temperature Insability and other problems.
The system used today, which is basically Standardized now, have a Low
Noise Preamp, feeding a Block Downconverter, (LNB) and feed the total
Fixed Bandwidth of the SAT Segment, (500 Mhz) to the SetTop Box at a
lower IF Frequency. (900 Mhz - 1400 Mhz approx) They still use DC Bias
on Coax Feeds to the LNB's, and these both power the LNB's, and also
select the Polarization of the FeedHorn.

Yes, it can be different in both phase and magnitude, determined by the length and diameter of the parasitic element. That's what you're doing when you adjust the lengths of the elements of a Yagi -- adjusting the phase and amplitude of the re-radiated fields from the elements.

That has nothing to do with not using an underground metal water pipe
that is present on the premises.

Some satellite dish sets also use a 22 kHz signal to switch between 2 local
oscillators in a "dual band" LNB.

that would really depend on the local AHJ (Authority Having Jurisdiction).. For instance, in the City of Thousand Oaks, CA, only Concrete Encased Grounding Electrodes (aka Ufer grounds) are allowed in new construction. (other grounding electrodes are permitted, but you better have the Ufer ground, and, of course, they would need to be bonded together, per NEC). With respect to my house, built in 1998, I don't think there is a bonding jumper from water pipe to the system ground at the service entrance (which is a Ufer ground). Obviously, there IS a jumper from the telco drop, the cable TV drop, etc. to the ground at the service entrance (and all the "drops" are actually underground services in plastic conduit). Partly this is because the water service comes in on the opposite of the house from all the "wired" utilities. I'll have to go take a look, though.

I believe the new code (which I don't have here to hand) does require that metallic water piping, if any, be bonded to the electrical system ground (presumably to eliminate "touch voltage").

I believe also, that the code prohibits use of a water pipe as the sole grounding electrode (NEC 250-(a)(2) in 1999 code, 250.53(D)(2) 2002,2005 codes). As always in code matters, what the AHJ says takes precedence.

As a practical matter, a properly constructed Ufer ground is probably lower impedance and more reliable than rods, wires, and pipes.

On 3 Apr 2007 07:28:45 -0700, "Jim Kelley" <jwkelley@uci.edu> wrote:

>I am not familiar with RADAR TR or anti-TR

Hi Jim, and others similarly unfamiliar,

Radar transmission systems have a wide and diverse design topology
that reveals all of the characteristics in an easy and accessibly
small space. Among these diverse applications are the already
mentioned TRansmit and AntiTRansmit tubes. Also are mode shifters,
polarization shifters, choke joints, directional couplers (classic,
not Bruene), isolators, circulators, and separators - a class that
includes what I alluded to, the "Magic T." This last is something
like the classic Hybrid Coupler.

Within these lines you can add either resistive, conductive or
dielectric windows, steps, vanes, and other configurations to create
tuned sections or transitions between sections. Each and all of such
elements readily reduce to wavelength and transmission line mechanics.
Their scale makes them "hands-on."

Returning to the TR/ATR tubes, they simply reside within the path of
the transmission line at a critical harmonic dimension. They consist
of a glass envelope, much like an acorn tube, and it contains a gas
and a simple spark gap and possibly a third exciter electrode. When a
sufficient electric field causes the gap to discharge, this creates
the short that is reflected to a nearby junction. The exciter
electrode is used with a bias to create a very low threshold for
firing. Needless to say, received signals are of insufficient
amplitude to fire the tube, hence the duplexing action.

This, then, creates a different topology between transmit and receive,
and it keeps the MW peak amplitudes out of the receiver front end as
the receive and transmit signal paths are identical otherwise.

Choke joints are passive in nature, but they also exhibit the use of a
tuned cavity that creates a conductive bridge across an otherwise open
gap between transmission line elements (this is a classic mechanism in
the rotary joint of the turning radar antenna).

The RADAR Transmission line systems offers the student vastly more
about transmission line concepts than the rather boring Lecher lines.

In this part of the world (Australia) an LV transformer usually serves many more premises (commonly 50 to 100), and the neutral wire (centre of the 3 phase 240/415 wye) is bonded to the premises earth electrode at each main switchboard (known as Multiple Earth Neutral or MEN), so premises earth systems are effectively paralleled using the neutral wire. The transformer neutral is connected to an earth electrode at the substation. The regulatory requirement for a MEN premises ground electrode here is just a 1.2m copper clad driven electrode, with no real performance requirement. Of course the earth system must be equipotential bonded to the metallic water service, and plumbers are at risk when they open up a metallic water pipe (they are supposed to jumper the gap to prevent electric shock).

This approach is probably less suited to 110VAC distribution.

Hi everyone,

I am new here, so please excuse my ignorance about antennas, or if I am in the wrong ng. I could not find any help getting the answer to my question by googling.

I have a cheap boom box radio that I recently bought at Walmart and it plays great music, and cd's, and cassettes. Unfortunately it will not play my favorite FM oldies station (97.5 MHz) either in my workshop, or my house (it plays several other stations fine). My other boom box will play the station (and its 20 years old), and they are both of relatively equal value (the older one is a brand name - Panasonic). If anything, I would think the new one should have 20 year newer technology in it, and it should play at least as good - dunno.

They both have a telescopic whip antenna (I hope that is the right terminology), and the new one will not play the station I want by either rotating the antenna, or moving the radio to different positions. I have tried everything. The only way it will play the station I want, is to put my hand on the antenna (or even around the antenna - ie I don't even have to touch it - interesting - I guess my body makes a real good antenna - I have always wondered about this phenomena). I tried touching it with other metallic devices (eg, wire, coat hanger etc), and it has no effect. The only way it will play the station is by getting near the antenna with my hand.

I see no way of mounting an FM antenna to the receiver (ie the antenna is factory mounted to the back of the radio.

I have a couple of questions if you will allow me :

- Is there anything I can do to the existing telescopic whip antenna (such as wrap it in aluminum foil or something else weird like that) that will enable the radio to pick up the station I want. And also, please explain why it plays the station I want when I put my hand on or around the antenna.

- I thought AM and FM antennas were different technologies (so to speak - eg amplitude modulation versus frequency modulation). How come portable AM/FM radios only have a single telescopic whip antenna (please excuse me if that is the wrong terminology). Is the whip for FM, and the AM is inside the radio, or it uses the cord (just a guess).

Any comments would be greatly appreciated. Thanks...Pete

Jim
I would hope you are aware that most concrete encased electrodes are not, in fact, a true UFER. In spite of that it is undoubtedly the most reliable electrode; which is not to say lowest impedance; commonly installed in homes. You are correct that an underground metal water piping electrode must always be supplemented with another electrode but the code still requires it to be used as an electrode were it is present on the premise. In my location the public water utility is entirely metallic, including the service laterals to buildings. It covers about fifty miles from north to south and more than thirty five miles east to west at it's widest point. That large an underground metal piping system has the lowest obtainable impedance to ground of any electrode on a premise served by the water system.

Hi,

I would say that the specifics are not that important. The DGA we
worked with had a cylindrically symmetric gain pattern that resembled
a "skinny" cardiod. The gain at the zenith was about roughly 12 Bic,
which fell to roughly 1 Bic at about 60 degrees (where the angle
measured is not the elevation, but the spherical coord theta). In
fact, you just made me realize that I fit the theta dependence very
well via the equation
0.00002399q^3 - 0.0031083q^2 - 0.025008q+11.0153
and that the phase as a function of theta was very linear, and that
the phase as a function of phi was "about" constant.

Hi Pete,

Neil's terse comment of taking back may ulitmately prove beneficial.

On the other hand you can just string up a lot of wire (higher is
always better) and simply wrap one end around the telescoping antenna.
Insulated wire or not shouldn't matter.

Source record: 43776

Pete,

The real difference between antennas and receiving FM stations versus AM stations has nothing to do with the modulation, but with the frequency on which these signals are transmitted. For optimal reception, you need an antenna that corresponds to the wavelength of the transmitted station. For AM radios, that is usually a real long length of wire wrapped around a magnetic rod within the radio. For FM, it is usually a telescoping whip antenna.

If you find yourself with two radios that are similarly-equipped in terms of antennas, but one gets your favorite stations while the other does not, then the one that does not is either broken or has designed-in lousy sensitivity.

How can you compensate for lousy sensitivity? If the low-sensitivity radio is _close_ to working (evidenced by its being able to hear your favorite station by putting your hand near the antenna) then you may be able to substitute a slighter better, directional antenna for the telescopic whip and get the stations you want. A cheap-and-dirty experiment would be to purchase a Radio Shack "Dipole FM Antenna [$3.00] and connect one lead to the whip (fully collapsed) and the other lead to a nearby ground connection in your workshop (center pin of a 3-prong electric outlet). Elevate the antenna as high as possible, and stretch the "T" sections horizontally. The best signal reception will be from the sides of the "T" -- so if you know the location of your favorite station's transmitter, you can rotate the ends of the T for best signal capture.

THEN AGAIN... you may just want to take it back to Wal-Mart for an exchange. Experiment with the available radios by collapsing the whip antennas and seeing which one gets the most stations and has the least "buzz" from the store's fluorescent lights.

You could look around for a GE SuperRadio III -- it runs about $40-50
nowadays, and has a separate FM antenna terminal you can hook up a
decent antenna to. This radio also has two speakers, a woofer and
tweeter, and sounds pretty nice, tho' it is mono.

Thank you Richard...that is the kind of comment I was looking for (I took Neil's with a grain of salt-there is absolutely nothing wrong with the radio). I was trying to be polite in my post, but I am way smarter than that.

I will try wrapping the wire around the antenna tomorrow and let you know what happens (is it okay to use phone wire which has several individually insulated wires in it). BTW could you please tell me why the reception comes in when I put my hand around the antenna (ie what is my body doing to the signal), and also answer my second question about one antenna for both AM and FM. Thanks again...Pete

... and some of them vary the DC voltage between two low voltages (like
14V and 18V) to switch between polarizations. The electronic package uses
12V and regulates it down from whatever it gets; the variable voltage is
strictly a control signal.

There's a lot of clever stuff running up that coax even if the
programming coming back down is sometimes gawd-awful.

OFF TRACK:
Funny ... I'm 64 and I have heard about bias tee's numerous times but did not know what they were. I just called them power adders. In fact, years ago I made one for a microwave transverter somebody gave me.

Now, I kid you not, I was reading a tech manual *today* and it included a diagram/purpose of a bias tee.

What are the odds of getting the same tech fact twice in the same day from two independent sources after 50 years of playing with 'trons?

Hi Pete,

No, it is still advice to consider. Your new radio does have the
performance of a lemon in comparison to your old set.

>I will try wrapping the wire around the antenna tomorrow and let you know
>what happens (is it okay to use phone wire which has several individually

>AM and FM. Thanks again...Pete

Yes, it is a mystery still....

Your body is a conductor, admittedly a very poor one, but the power
levels we are talking about, and the currents involved don't ask very
much. The wavelengths involved for FM are about your height. If we
shift to AM, you would have to be the Jolly Green Giant (hence hand
waving usually doesn't do much good). That you don't even have to
touch the antenna is also an indication in the small power necessary,
it is more about your height and proximity.

Multi wire, such as you have, will make little difference. However,
this is not to say that things won't remain marginal. You do have the
experience with another radio that works in the identical environment,
so that suggests some hope. There are "magic" lengths of wire, but
you can escape that discussion by crafting various different lengths
by bending, trimming, but still keeping things high (all of this is
predicated on putting the antenna into the sight of the transmitter).

The same antenna is NOT for both bands. The AM antenna is undoubtedly
the old stand by we call the loopstick. This is a long rod of ferrite
material with a coil or wrapping of wire - you've probably seen these
before. A car antenna certainly does double duty, but this is not
generally found in portable radios. This is because the car radio
sits inside a metal cage that demands an external sky hook.

Thanks Larry...You top posted, so I will to. I really am a technical person and know a little bit about this stuff, and there is no doubt that the tuner/antenna circuitry in the older Panasonic is more sensitive (ie better). I will try Richards comments and let you guys know what happens. And if that doesn't help than maybe I will try your suggestion. Thanks for taking the time to comment. Have you ever been to Walmarts. You are lucky if you are able to plug anything in. Believe it or not I did plug the display of the one I bought in. Most of them are all a mess and you can't plug anything in :-) .

Thanks for your reply Roy and, while I'm at it, thanks for your continued contribution to Amateur Radio.

I didn't mention that I have a homebrew 1:1 current balun installed at the antenna feedpoint to eliminate common mode currents which would otherwise result from the off center feed. Would my EZNEC model still not be adequate? (I also didn't mention the 4:1 balun in my antenna tuner which I am accounting for in my comparison.) Also there is probably some coupling of the feedline to the antenna field due to geometry, but I tried to keep the feedline perpendicular to the feedpoint as much as possible. I believe I read in the HELP file that EZNEC does not model this type of coupling. Am I correct on this point? I am not experiencing any issues with radiation off the feedline at my operating location, so I believe I've done a pretty good job with the balun and feedline routing.

Would you still recommend I don't pursue modeling of my OFC with EZNEC at least as far as transmission line and feedpoint parameters go. How about radiation patterns given the additional info in this post?

If I model the antenna feed with two additional wires will the limit on segments in the demo version of EZNEC start having an appreciable impact on the quality of results? I'm probably going to get the full version anyway but I am curious about the affect that segment limits has.

One more question. Is there a way to set antenna orientation in EZNEC so that it coincides with my actual antenna end to end compass bearings? This would allow me to use the "bearings" option in EZNEC directly. It appears I have to measure X - Y offsets to do this and can't use a simple circular (degrees) input in EZNEC to do this.

All of this is just an outfall of my interest in RF antenna technology. The antenna is operating fairly well for stateside operation.

Thanks again.

> for grounding.
> Roger Halstead (K8RI & ARRL life member)
> (N833R, S# CD-2 Worlds oldest Debonair)www.rogerhalstead.com

Roger is correct here. Underground water pipe electrode is no
longer sufficient as the earth ground in most locations for a long
list of reasons. Yes, that water pipe must be bonded to the AC
electric so that plumbing is electrically same voltages as everything
else inside the house - human safety. Public utility water system may
have voltages different from AC electric if the two are not bonded -
as has been observed when a fault was created outside the building.
Destructive currents entering on that water system must be eliminated
by being bonded to AC electric.

Many other reasons why AC breaker box must be bonded to the cold
water pipe. Yes cold water pipe may act as an earthing electrode.
But it is no longer sufficient as the earthing electrode.

An earthing electrode - one that all utilities must use - is not the
water pipe. All utilities must connect to a separate and dedicated
earthing electrode defined by code (as defined in Article 250.52 A -
paragraphs 2 through 7). The code defines 7 types of earthing
electrodes. The only electrode not sufficient is cold water pipe -
paragraph 1.

For lightning, an antenna (or satellite dish) is typically treated
as if a separate structure as demonstrated in this application note:
http://www.erico.com/public/library/fep/technotes/tncr002.pdf
Antenna wire must connect to the same building 'single point' earthing
electrode. IOW any wire in any cable going to the station must first
connect to that single point earthing electrode (either by hardwire or
protector) before entering the building. Best is to have the antenna
earthing also connected, by underground wire, to that same single
point ground.

This for lightning protection is beyond what is called for by
National Electrical Code for numerous reasons. First, NEC only
addresses human safety. The OP is asking about transistor safety.

Second, the code does little to address impedance. Grounding for human safety is mostly about resistance - not impedance. Third, any grounding system dependent on some other trade (ie plumber) is no longer considered safe or sufficient.

A ground system must meet NEC requirements. Then it must exceed those requirements. For lightning protection, a cold water pipe is not longer considered a good solution because that earthing electrode is just not sufficient.

Also better is to earth lightning rods and antennas before that ground wire connects to a building's single point ground. Notice the underground wire connection between antenna earth ground and building earth ground.

And finally a purpose of earthing that is beyond what the NEC requires. A station needs earthing that provided both equipotential and conductivity. Code concentrates on conductivity. But for equipotential, we do things beyond what is normally sufficient for human safety. We install Ufer grounds or halo grounds that completely surround the protected facility. We relocate all utilities so that each wire in each cable makes a 'less than 10 foot' connection to that common earth electrode. Any exception to the single point earth ground (as defined in code) is not permitted when also earthing for transistor safety. Route earthing wires to be separate from all other wires, no splices, no sharp bends, not inside metallic conduit, etc. All earthing wires remain electrically separate until all meet at the single point ground. Conditions beyond what code demands or permits.

Consider with care information in that figure in:
http://www.erico.com/public/library/fep/technotes/tncr002.pdf
Things recommended are not immediately obvious. Reasons for this involve both equipotential and conductivity. Both are required for station protection.

3621. gamma match 70cm handheld

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-04 10:40:12 UTC
From: Kurt <ksaves2@sbcglobal.net>
Message-ID: <%FPQh.1209$zC.237@newssvr22.news.prodigy.net>
Source record: 43638

Hi,

Am trying a homemade 7 element handheld beam I'm making for 70cm with .25" brass stock. Have a little junction box I have mounted on the beam with a male socket so I can use a BNC cable for the radio connection. Does it matter what size/type wire I use to connect the socket to the brass element and the Gamma match element inside the junction box? I want to use a socket so I can use different lengths of cable as opposed to hardwiring the cable to the antenna.

Thanks loads,
Kurt

>
Actually, it might be the reverse, depending on what exactly is happening.

I have a all in one stereo I got at a garage sale. It had lousy reception of
a non-local station that is always receivable here on other radios, even lousy
ones. I naturally thought the antenna was the problem. But I did something
and realized I likely was attenuating the signal, and the issue wasn't
"not enough antenna" but too much. I took off the whip antenna, and that
thing gets perfect reception on that non-local station, whereas before it
was noisy.

Clearly, the stereo was being overloaded by local signals, which impacted
on it's ability to receive the strong but comparatively weaker non-local
station. Removing the antenna attenuated the local station(s) enough that
the stereo didn't overload, but the non-local station was still strong
enough to be received fine.

Most consumer broadcast receivers are too sensitive if anything, because
they don't handle strong signals that well, yet the strong signals
overloading them make them useless for receiving distant signals. A
less sensitive receiver wouldn't be as good for distant reception, but
the local signals wouldn't mask those distant signals with overload.

I don't know if this is the case here, but it is worth looking into
since it's the last thing people generally expect. I notice when I
got a Grundig portable sw receiver at a rummage sale in September, the
manual specifically states to keep the whip antenna shorter when on
the FM broadcast band (the antenna being longer for the shortwave
bands), and having been prompted by the manual and experience, I do
notice that not so great reception on the FM band is improved when
I shorten the whip antenna.

I havent had good results using a gamma match on 70cm. Im not sure if
its something I am doing wrong or maybe everyone else has problems
with gamma matches on this band too. I have become a quagi fan for
this band.

Yes, all explained in my energy analysis article.
Personally, I wish whoever introduced virtual
reflection coefficients had not done so.

As Thomas said, Roger is correct if the underground water service pipe
is plastic.
Missing is any of the ï¿½long list of reasonsï¿½.

> earthing electrode defined by code (as defined in Article 250.52 A -
> paragraphs 2 through 7). The code defines 7 types of earthing
> electrodes. The only electrode not sufficient is cold water pipe -
> paragraph 1.

The code says (250.50) all electrodes listed in 250.52-A-1 through 6
MUST (where present) be connected together to form the earth electrode
system. 250.52ï¿½A-1, which is conveniently missing from w_ï¿½s list, is
metal underground water pipe (at least 10 feet metal underground).

ONLY if the pipe is not 10 feet long underground is bonding used instead.

Water pipe requires a ï¿½supplementalï¿½ electrode. That is because the
metal pipe may in the future be replaced by plastic.
From the National Electrical Code Handbook - same publisher as the NEC

ï¿½The requirement to supplement the metal water pipe is based on the practice of using plastic pipe for replacement when the original metal water pipe fails. This leaves the system without a grounding electrode unless a supplementary electrode is provided.ï¿½

Requiring a supplemental electrode does not indicate there is any defect in metal pipe as an electrode. As Thomas indicates, it is likely by far the best electrode available in urban areas with metal supply.

Earthing connection of other services, like the phone NID, may be made to the water pipe within 5 feet of the entrance to the building (the connection of the power earthing conductor is in the same 5 foot span).

> We install Ufer grounds or halo grounds that completely
> surround the protected facility.

From
http://www.lightningsafety.com/nlsi_lhm/grounding_definitions.html
ï¿½Halo Grounded Ring: A grounded No. 2 wire, installed around all four walls inside a small building, at an elevation of approx. six inches below the ceiling. There are drops installed from the halo to the equipment cabinets and to waveguide ports, interior cable trays etc. Halo rings serve as connector points to achieve ground references of interior metallic objects. These, in turn, are connected to the main ground bus bar.ï¿½

Perhaps you mean ï¿½ground ringï¿½?

The code now requires a Ufer electrode in new construction with concrete foundations or footings.

The number of watts inside a coaxial transmission line
is understood by any any rational person to be distributed
over the area of the coax. With a fixed-given unit-area,
the Poynting Vector is customarily given in watts, not
watts/unit-area. The same thing applies to watts within
a laser beam.

You are probably right about published white papers. You
are wrong about the engineering profession. All engineers
need to do is get close enough.

> added. Kindly explain where the 'reflected power' on
> this new section of 450 Ohm line goes.

It doesn't leave the 450 ohm line as long as the generator
sees 75 ohms as a load. Here is a similar example:

source---75 ohm line--+--1/2WL 450 ohm line---75 ohm load

Where does the reflected energy on the 450 ohm line go?
Since there is a 75 ohm Z0-match at point '+', it circulates
between the load and point '+'. Decrease the length of the
75 ohm line by one inch until it doesn't exist anymore.
The same conditions continue to exist all during that time.
The reflections at point '+' disappear in the process of
wave cancellation which is a type of permanent interference.

>> Now consider that the 75 ohm line can be one foot
>> long and everything is the same as the 1WL of 75
>> ohm line (except the delays).
>
> This would be quite incorrect.

No, this would be 100% correct. One foot of 75 ohm coax
is enough to establish a 75 ohm environment. A 75 ohm
load on the source is enough to establish a 75 ohm
environment. Please see:

There is no simpler amplifier than a single transistor
with a resistor in the collector circuit. That's the one
everyone starts out with in Electronics 101. Replacing
the collector resistor with an RF choke is a complication
that comes later.

> Rather, I see a suggestion that the

I agree 100% and have said so in the past. If a source
delivers 70.7 volts to a 50 ohm load, the source impedance
doesn't matter except for efficiency.

High Matt,

For most antennas, the phase versus angle w.r.t. main lobe is not given. The same is valid for the phase center. When they give it, you should have a means to verify it.

As long as you make your array from same antennas, phase variation for each antenna will be the same and will cancel. Of course this is not true when you want to make time of arrival measurements for satellites under different elevation angle.

Another thing that might be of importance is the polarization. This also varies with antenna orientation.

If it really matters, I would suggest that you use a EM-field solver to find the full radiation pattern (phase, magnitude and polarization) for your antenna. If you consider patch like antennas, a NEC based simulator is not the best choice, probably you have to divert to expensive commercial packages. If money is available, you may hire somebody. The learning curve can be lengthy to get trustful results from simulation.

Technically spoken, it can be measured also, but you need a combination of good measuring equipment and a person that is very well into wave propagation. I'm not deep into GPS but is it possible to calibrate the antennas with the GPS system?

Of course this does not answer your question, but I hope it will help you a bit in finding an answer.

Wim

Hi Richard...Make sure to read Michael Black's interesting info in this thread. I definitely believe the radio (cheap as it may be) is doing exactly what it is designed to do. I do not believe it is a lemon, and there is no doubt in my mind the older Panasonic has better circuitry in it (it is a better set and has a graphic equalizer also - the newer one doesn't even have bass/treble controls but it sounds good), but they are roughly comparable.

Actually, the old one probably costs quite a bit more (on a relative basis) considering how cheap you can buy this stuff these days compared to the price twenty years ago. Just for your info, I have an old Electrovoice stereo receiver downstairs (with dials/knobs) and it still works fine after 36 years.

Also FYI, I have a new Sherwood stereo receiver upstairs (with the fm antenna that came with it installed), and it also picks up the station I am talking about weaker than the other stations, but I was able to tweak the antenna and it comes in acceptable. It is interesting that the old Panasonic boombox has no trouble. Sorry if I am going off on a tangent. I have more comments below :-) ....Pete

Exactly two reasons: mu, and epsilon.

A physical boundary is neither defined by, nor affected by voltage, current, irradiance, luminosity, power, wealth, energy, phase of the moon, sun spots, kharma, or even gravitas.

Has this become a new point of contention, Cecil? You've said that you always claimed that waves only reflect from physical boundaries. And that's all I'm saying.

3638. Lightning 'liability' ?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-04 19:50:45 UTC
From: KE5MMJZ <spam@artair.com>
Message-ID: <slrnf180co.7j9.spam-collector@k6.artair.com>
Source record: 43654

As a new ham, I am considering erecting a tower for
my antenna(s). As part of my research, I've been
reading about lightning protection, and now feel
I have a fair understanding of what I need to do
in order to protect both my radio gear and my home.
However, the thought occurred to me that if I
ercted a tower it would probably increase the odds
of lightning striking either it or a nearby object,
and while my house might be protected (or at least
I would be the one choosing to take the risk), what
about the neighbors? Even if the strike would be
directly on my tower, from what I've read there
could be enough induced voltage/current to damage
the 'unprotected' appliances of my neighbors, and
they might blame me for their losses (or even if
it doesn't hit the tower, they may still see it
as the cause of a nearby strike).
Has anyone heard of any such cases or am I
just worrying about the highly improbable?

Thanks,
Frank
KE5MJZ

Frank,

The existence of a tall conductor provides a measure of protection to nearby structures. The zone is often defined by a "ball" of radius equal to the height of the tall structure that is rolled on the ground to rest against the tall structure, and structures between the contact with the ground and tower, and under the ball are considered protected by the tall structure, ie that lightning is much more likely to strike the tall object. In this way, a tower often protects the nearby equipment hut from direct strikes.

Having said that, there are two other effects you must consider:
- the way in which the discharge current on the tower is dealth with; and
- the fields in the nearby area from the discharge current.

The usual approach is to try to shunt as much of the discharge current to ground. Nevertheless, some will enter your premises and you should pay attention to equipotential bonding and single point earthing techniques to minimise the voltages impressed across equipment interfaces, voltage that may cause damage.

It is not just about equipment, personal safety is more important, but provided you use earthing conductors sufficient to survive the lightning discharges (and people of do not) and equipotential bonding, then personal protection is fairly easily achieved.

Even if you have dealt with minimising interface voltages in your own premises, the discharge current may give rise to a surge on the power

lines or metallic water services that couple to your neighbours relative to each other or telecommunications services. It is conceivable that a discharge to your tower might not cause damage to your installation but could damage appliance in neighbouring premises... so I wouldn't call your tower as protecting neighbours.

Owen

> good job with the balun and feedline routing.

EZNEC does model this type of coupling from wire to wire, but no coupling to a transmission line model. So the coupling will be accounted for only if you model the transmission line as wires.

Keeping the feedline perpendicular to the antenna isn't sufficient to eliminate coupling when the feedpoint is offset, since the line will still get unequal coupling from the two antenna sides. About the only way to positively reduce it to a small value is to use multiple current baluns spaced about a quarter wavelength or closer. The common mode current might otherwise be high or low depending on the feedline length and the length of the path to ground. Without modeling the entire path, the accuracy of the EZNEC model will depend on how successful you've been in reducing the common mode current to a low value. It's often difficult with an off-center fed antenna.

> Would you still recommend I don't pursue modeling of my OFC with EZNEC
> at least as far as transmission line and feedpoint parameters go. How
> about radiation patterns given the additional info in this post?

I'd always be suspicious of the result unless I verified that the common mode current on the line is low. You can, of course, measure it with a simple transformer made from a clamp-on ferrite core clamped over both feedline wires. Use about 10 turns for the secondary, and terminate the secondary with 50 ohms. That also allows you to put the detector at a distance, connected to the transformer with 50 ohm line, with the termination at the detector end.

> If I model the antenna feed with two additional wires will the limit
> on segments in the demo version of EZNEC start having an appreciable
> impact on the quality of results? I'm probably going to get the full

> has.

You'll probably start getting a noticeable change in results when the segment lengths exceed about 0.1 wavelength.

> One more question. Is there a way to set antenna orientation in EZNEC

You can either define the antenna wires to be in the correct orientation to begin with, or you can define them in a convenient way then use the Rotate Wire feature to rotate them to the desired orientation. If you prefer to work with compass direction rather than degrees CCW from the X axis, you can chose this in the Options Menu (Angle Convention selection).

Kurt, if the connection is real short, it won't matter much and will be compensated by the gamma trimming. Keep in mind that the diameter of the gamma arm and spacing relative to the driven element itself are very important, and to the extent your connection is an extension of that, it will become important if it has appreciable length.

Gamma matches are very sensitive to dimensions around the gamma arm, so they are not a very good match for an antenna that might get knocked around.

I believe that the latest research indicates that the "rolling ball"
isn't as accurate as once believed (or necessarily better than the older
"cone of protection"). But the difference might be in the noise floor
for most ham installations.

> Michael VE2BVW

Michael...you were absolutely correct (100%) about shortening the whip for FM broadcasts. I shortened the whip to its fully collapsed position and it worked, and the station I wanted came in at an acceptable level. Great info. So now my logical question is why are the FM whip antennas even extendible if they play better fully collapsed. I guess it depends on a bunch of variables such as power of the transmitter and location of where the signal is being transmitted from. I know from past experience that extending the antenna can help sometimes.

But shortening it worked - what is the quick logic if you don't mind. I know that everything is frequency and wavelength and they are inversely proportional. I would have never thought that shortening the antenna would have solved the problem - I even thought I tried that before, but I must not have stayed with it long enough. Thanks again to you and everyone else for all your help :-) .

if the lightning is close enough to strike your tower, it was going to hit
in that general area anyway. your tower has no effect once you get up to
the heights where lightning starts... it can only effect that last little
jump to connect to the ground where the 'cone' or 'ball' of protection area
is commonly considered.

Agreed Jim. The case is better for the nearby equipment hut than the
typical residential building near a 50' tower.

BTW, the "rolling ball" is the recommended approach in Australian
Standard 1768-1991 which I think is still current.

I searched thru Google and I see there is a lot of work going on with
respect to tilting in the GHz area. Apparently some antennas come
equiped with remote mechanical as well as digital type switchers. I
found one commercial vertical antenna that was FIXED at a 3 degree
tilt which is about what I found with a high frequency version for max
vertical gain. Seems like the majority are going for mechanical
tilting as digital delay style tilting is having an adverse action on
the beam itself. I cannot find any literature that supplies technical
backup so I suspect they are the result of emperical work and not
mathematically as I have.It does seem that
many are using tilt angle for accuracy in TOA for various reasons.

By the way I have found that with cluster form this tilt angle is progressive with respect to close spaced elements in both horizontal and vertical forms. Seems like the commercials are spending a lot of money with repect to tipping for WiFI which requires extreme accurracy between nodes and where inaccurracy becomes progressive in deteriation. All very fascinating at least for non amateurs.

I haven't heard of it. Just make sure that everything is grounded
according to the National Electric Code (NEC). There are sections
devoted especially for towers at residences.

I say this as one who works in an industrial environment with large
free-standing towers. Our gear must stay online with five nines of
reliability. We routinely take direct hits on our microwave gear and
nothing happens. It goes to ground. We may not notice a thing except
for a few connections which have been welded together ;-)

From: Wayne <mygarbagecan@verizon.net>
Message-ID: <0CYQh.11100$P84.5052@trnddc07>
Source record: 43666

OK, I used to be able to do this years ago, but I can't seem to find the right references now.

If an antenna reflection coefficient is measured at, for example. 0.333 at -100 degrees, how is Z calculated? I think I can do this with a smith chart, but the result does not match my attempted calculations.

TIA
Wayne

Hello Wayne,

The first reference I can give you is in "Theory and Problems of Transmission Lines," by Robert Chipman, in
Schaum's Outline Series, Page 128, Eqs. 7.9a and 7.9b.

If you don't have access to Schaum, I'll reconstitute the equations for you in Word, and send them via email.

In addition, I ran across these equations a day or so ago on this NG--I'll try to find them and direct you to
them on this NG.

Truly, you have constructed a world view that is much more
complicated than necessary.

Consider the 75 Ohm resistor at the right hand end of a 75 Ohm
transmission line. The load is matched to the line and there
is no discontinuity and (dare I say it?) no reflection.

Want a generator at that end? Put an ideal current source
in parallel with the 75 Ohm resistor. What do you have but a
generator with a 75 Ohm output impedance. And no discontinuity.

Do all the above with a 50 Ohm resistor. As a load, the 50
Ohm resistor is a discontinuity with reflections. As a
generator it has a 50 Ohm output impedance and there is a
discontinuity.

Is not the symmetry rather enticing? And simple?

And using superposition, you can analyze the incident wave
and its reflection, and along with the generated wave, sum
them to obtain the total system response.

Truly elegant. And all so simple.

...Keith

The expression for Gamma that springs to mind is (Zl-Zo)/(Zl+Zo).

Rearranging the terms gives Zl=-Zo(Gamma+1)/(Gamma-1) doesn't it?

Owen, l just now sent Wayne the equations from Chipman, using the eq editor in Word.

In case others would like the equations I'll try to format them here without the Word editor.

R/Zo = (1 - rho squared)/(1 + rho squared - 2 rho cos phi)

X/Zo = (2 rho sin phi)/(1 + rho squared - 2 rho cos phi)

Walt, I take that to use rho to mean to magnitude of the reflection
coefficient Gamma.

My formula appears correct for Gamma, and the answer to Wayne's example
is 36-j27.

There is an uglier formula with tanh terms in it that gives the impedance at a distance along a line with a given propagation constant... but it is much more complicated to calculate than my expression when the distance is zero.

Pete wrote:
"So now my logical question is why are the FM whip antennas even extendible if they play better fully collapsed?"

Length is adjustable to tune the antenna to resonance so that excess reactance does not block too much signal from the receiver. Resonance depends on the station you want to receive.

Wavelength = 300 / MHz

At 100 MHz, wavelength = 3 meters

If the best antenna length were 1/4 wavelength, length would be about 0.75 meter = 75cm/2.54cm/in.= 29.53in. which may be shortened by 5% for "end effects" which calculates to about 28 inches for a 100 MHz station. Higher frequency stations may require shorter lengths and lower frequency stations may require longer lengths. We don`t know the design of the radio and what inherent reactance may reside inside. So, we really don`t know how long the adjustable antenna needs to be.
It is far better to experiment with the length of the antenna to get the best results.

Some radios use the same antenna for several bands of a multiband tadio. So adjust the antenna if necessary for best results.

Best regards, Richard Harrison, KB5WZI

These appear to depend on Zo=Ro to be correct, perhaps they would be more correctly expressed using Ro instead of Zo.

Owen, for historical accuracy, at least in the US, prior to 1950, rho, sigma, and S were used to represent
standing wave ratio. The symbol of choice used to represent reflection coefficient during that early era was
upper case lambda. However, in 1953 the American Standards Association (now NIST) announced in its publication
ASA Y10.9-1953, that rho is to replace upper case lambda as the standard symbol for reflection coefficient,
and SWR to represent standing wave ratio. Most of academia responded to the change, but a few have not. I
don't know about Australia, but in the US lambda is rarely seen as the symbol for reflection coefficient.

WRT Ro vs Zo, I was simply copying directly from Chipman, where Zo is routinely considered the characteristic
impedance of a transmission line, and where it's usually considered sufficiently low loss to the thought of as
Ro.

Dave wrote:
"I would like to propose a grounding arrangement for my (hypothetical) antenna and get some feedback on it."

Assuming the tower is not base insulated, start by grounding each leg of the tower with a no. 6 AWG or larger cable directly to its own ground rod.

Best lightning protection comes from folded driven element antennas grounded directly at the tower top or other mounting point and connecting the antenna with coax which is grounded again at the tower base. If a folded driven element is not used, a short-circuited quarter-wave stub can be connected directly across the antenna drivepoint to supply the grounding to the tower that a folded element provides.

Standard practice requires a no. 6 AWG or larger cable directly connecting the base of the tower to the ground connection used by the electrical service to the site.

For enhanced protection, large RF chokes as used in tower lighting circuits in broadcast stations, are placed in each power wire, including the neutral, between the electrical service and the radio connected to the antenna. A-C capacitors are connected between each end of the high-current chokes and a common connection directly to the station ground. If there are 3 wires you need 6 caoacitors. Across each capacitor you need a metal oxide varistor appropriate for the line volts and the joules you may be called upon to dissipate when lightning strikes. We also shunted the capavcitors with conventional thyrite arrestors to back-up the MOV`s. This pi-filter with arresters worked like gang busters. It is not excessive but did prove necessary for solid-state equipment protection.

Best regards, Richard Harrison, KB5WZI

I read the other responses and have no quarrel with them. However,
I have seen a commercial uhf yagi with a gamma match. It was on
the side of a building and was probably cut for the 450 - 470 MHz
business band; it looked just a bit smaller than my 70 cm antennas.

My point: It can be done, assuming the antenna I saw wasn't a
total POS!

Thank you Richard. I understand what you said. This was a lower to mid frequency station (97.5 MHz), and it required a shorter length, but other stations right next to it came in fine at a longer extension. This is weird stuff, and its obviously dependent on the radio guts and what is going on with that one station as far as location and power, etc. It is refreshing to be in a newsgroup where people are helpful, and not condescending and vulgar like so many others if you know what I mean. Thanks again to you all.

Chipman's formulae that you quoted work correctly if rho means the
magnitude of the complex reflection coefficient (rather than the
(complex) reflection coefficient as you say above).

The formulae were probably written when we used slide rules and worked
out the real and imaginary parts separately, whereas today with access to
tools that treat complex numbers as such, we can carry a complex value
through calculations as a single value then separate out the real an
imaginary parts at the end. There is also no real burden in treating Zo
as complex instead of the lossless / distortionless line approximation.

The different notation is painful, isn't it. I write Gamma to mean
uppercase-gamma, and use Gamma for the complex reflection coefficient,
rho for the magnitude of Gamma, lambda for wavelength, don't use Lambda
(I don't think), and gamma for the complex line propagation constant. It
think it is a fairly common convention, but if what you say above is
literally correct, it is not compliant with ASA Y10.9-1953.

Hi Rick,

A stub of coaxial cable will work... approximately 30pF/foot for 50 ohm types... approximately 20pF/foot for 75 ohm types. Aside from the low cost, the spiffy thing about using a coax stub is that, with a pair of wire cutters, it makes the trap easily tunable.

The breakdown voltage will be much higher for a cable with a solid polyethylene dielectric than for the foamed PE cables: http://www.belden.com/pdfs/Cable101/coaxrefc.pdf. In that datasheet, 8214 (RG8/U w/ FPE dielectric) is good for 300V RMS, while 8237 (RG8/U w/ solid PE dielectric) is good for 3700V RMS. You might not think your 100W would need much insulation (70.7V at 50 ohms) but, your trap may *not* be at a 50 ohm point. Hint: to maintain the cable's breakdown voltage, let the center conductor & dielectric protrude beyond the shield. Otherwise, the free-hanging end of the stub may arc over. I learned that trick when building an 80/40m trap dipole... flashed it over a few times (running a kilowatt) before I noticed the soot!

I agree; rigidity of the matching section is all-important. But, I don't think it'd be too hard to accomplish, using a chuck of plastic/teflon block... the gamma rod would be only a couple of inches long.

In my days installing/maintaining FM receivers for background music (67 KHz SCA subcarrier), I ran into that a few times. In one installation, I installed our standard 3 element yagi on the roof and aimed it toward our transmitter. I had line-of-sight to our transmitter some 30 miles away (48.2 Km for our Canadian friend) but had horrible reception.
Our station was on 98.9 MHz (35KW), and at the top of the hill from my receiving location (90° azimuth) , were 3 TV (Ch 4, 5 & 7) and 2 FM stations (98.1 MHz & 100.7 MHz). I surmised the combined 716KW of those stations was overloading the receiver. A dipole made from some lamp cord wire, stapled to the ceiling of the room and fed into 75 ohm coax worked perfectly.
Sometimes simplest is bestest! :-)

Something to keep in mind is that a short open circuit stub of small coax is a relatively lossy capacitor, and a lower loss capacitor can be made by cutting the cable in two and paralleling the two pieces.

For example, 2m of RG58C/U has a reactance of about 68 ohms at 10MHz, and a Q of only 135. 2 parallel pieces of 1.1m length has the same reactance, but double the Q, but still nowhere near the Q you expect of those doorknobs.

> 73, Cecil, w5dxp.com
Close but no cigar. The (now often automatic) antenna tuner is used to
transform the native impedance to the transmitter to match the conjugate
transformed impedance of the antenna at the transmitter end of the
transmission line. The effective result is that the incident energy
arriving at the antenna "sees" a matched load and goes out to free space
instead of bouncing off the transmission line to antenna interface.
This is also why better antennas have reasonable (not far off matching
impedance) characteristic impedances; they do not require matching networks
physically placed at the antenna itself.

3676. 4nec2 advice sought...

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-05 10:01:19 UTC
From: Iain Kelly <no.spam@m0pcb.co.uk>
Message-ID: <ev2hbr$56c$1@netty.york.ac.uk>
Source record: 43592

Greetings to one and all,

Hopefully someone will be able to advise me on the following, being very new to NEC modelling I've hit a stumbling block.

As part of my Masters dissertation (In RF Engineering) I am working on developing an N element antenna array in the V/UHF area of the spectrum for a field system (non-amateur). It's nothing that's not really been done before, but I'm taking the practical 'ham' approach to it. Anyway this is only background to my question, and is not really too relevant.

I decided to have a go with some modelling software before actually building an array ad testing it. It just so happens that I had installed 4nec2 many moons ago though I'd never used it. For some reason I had it in my head that modelling an antenna was difficult. Well I'm sure it takes a lot of thought to do a complex model, and the simple models I've done so far have been quite a learning curve, but a fun one at that.

Anyway, I have modelled what is essentially a 4-square above ground and so on, which is fine. The next stage was to make the array out of dipoles. This went fine when modelling in free space, centring around z=0. I get lovely 3D plots etc, wonderful!

Now I want to model this dipole arrangement as if it was mounted on a tower, i.e. not at z=0. So I move all the elements up to the correct height and add in a real earth (which adds itself at z=0). That much is fine. When I then run the model the radiation plots are still all centred on z=0.

Now, logic says to me that the radiation should be coming from the driven antenna elements rather than a point on the ground beneath them.

Am I missing something really simple here?

Many thanks in advance. :-)

Hi Iain

You are displaying the far field radiation pattern, not the close-up
energy density...

ie the antenna and height above ground is very small compared to the
radiation pattern being displayed.

Cheers Bob

Aha, so it's just a matter of scale in the plot then? That's what was confusing me. My mind was looking to directly compare the 3D pattern generated with the antenna structure. It makes a bit more sense now.

Cheers,

Yet that violates the convention that reflected energy
absorbed by the source was never sourced. Why do you
think that convention was adopted in the first place?

> Is not the symmetry rather enticing? And simple?

Apparently it has enticed you to ignore reality. This
argument has been raging for a good 20 years now. Some
of the brightest engineers in the world still disagree.
Your simplistic theories are easily disproved by a
bench experiment. Why you cling to them is strange.

> And all so simple.

Make that simple-minded.

I may have misread Keith's posting. I thought we were
talking about sources. Is the above posting about a
75 ohm load devoid of any source?

Consider a 75 ohm load resistor terminating a 75 ohm
transmission line. There are no reflections and the
system is called "flat". Now add a source at that
load end. There will indeed be both forward and reverse
traveling waves.

I am skimming thru the Propagation chapter of the ARRL handbook, and I am having a difficult time understanding the shortening of wavelength and the retainment of frequency. They have an equation showing that wave velocity is: c = f*w (c = m/s, f = frequency, w = wavelength). It also states that during refraction "the wavelength is simultaneously shortened, but the wave frequency (number of crests that pass a certain point in a given unit of time) remains constant."

I don't understand. If the wavelength is shortened, then shouldn't the frequency increase instead of remaining constant?

> traveling waves.

Yes indeed. And the beautiful part is that you can use
superposition to analyze the two directions independantly.

The forward wave reaches the 75 Ohm termination and there
is no reflection. The reverse wave leaves the 75 Ohm generator
and heads down the line.

The total response at any point on the line is the sum of
the two waves at the desired instant at that point.

This works in all cases:
- The waves can have differing phases.
- The waves can have different frequencies.
- The signals do not have to be sinusoids. It works for all
waveshapes: step, square, pulse, you name it.
- The signals don't need to have the same waveshape, though
the arithmetic becomes quite tedious for complex wave
shapes.

The generality is astounding.

Of course sticking to steady state sinusoids at a single
frequency does offer useful simplifications such as 'effective
impedance', 'forward power' and 'reverse power', but care must
be taken with their application since they are not part of

the general solution.

This frequency is relevant ONLY for vacuum (or with a very, very slight alteration) air.

Now, it may seem that all air is air, but no. There are slight variations here too that on the global scale small shifts make large changes. Those small shifts are accounted for by pressure, water content (vapor), and temperature.

Refraction occurs when an EM wave, having frequency f and wavelength w enters a medium in which the speed of propagation (speed of light) is different than vacuum. A medium with an index of refraction greater than one produces a speed of light which is slower than in vacuum (index of refraction is simply the ratio of vacuum speed to speed in that medium). This changes the proportionality between frequency and wavelength. Since w = c / f, the slower speed at a given frequency will now have a correspondingly shorter wavelength. And, as f = c / w, the slower speed at a given wavelength will now have a correspondingly lower frequency.

I hope that makes sense.

'c' decreases because of the fractional velocity
factor in a transmission line. The decrease in 'c'
compresses the wavelength but doesn't change the
frequency. 'c' is less in a transmission line than
it is in free space. The speed of light in RG-213,
for instance, is 2/3 of the speed of light in free
space.

frequency stays the same, but since it's moving slower, c is smaller, so lambda (wavelength) is shorter.

Same thing goes on in coaxial cable.. the wave propagates in a dielectric with a propagation speed, say, 66% of the free space speed. In such a case, a one wavelength long piece of coax for 30 MHz is 6.6 meters, not 10 meters (the free space wavelength)

The challenge, of course, would be in getting the opposite phenomenon to occur (propagation faster than free space)...but that's a topic for a different day.

True for any *passive* point on the line. Apparently
not true at the heart of a dynamic active source which
is easy to prove on the bench. Seems to me that based
on real-world bench experiments, we must conclude that
the principle of superposition doesn't apply to sources
because the act of applying DC power to the source
changes the configuration of the system which is a
violation of the principle of superposition rules.
Ramo and Whinnery warn us about attaching any real-
world significance to the power dissipation in an
equivalent source.

Obviously, if any system conditions change when power is
applied the basic rules for the superposition principle
have been violated.

Hopefully, you are beginning to understand why the
convention of 100% rejection of reflected energy
by the source was adopted.

About Zo being reasonably approximated by Ro, or not:

I made a note to myself some time ago, and I believe it's reasonably
accurate, that neglecting dielectric loss, for a TEM line, given Zo =
Ro+jXo, then to a good approximation

Xo = -0.180*Ro*A*Vf/f

where A = line attenuation in dB/100ft
Vf = line velocity factor
f = frequency in MHz.

So for small diameter 50 ohm polyethylene dielectric line at 1.8MHz, the worst case for most ham applications, Xo/Ro is about .18. For that, I used 2.7dB/100ft for RG174 type line. That's getting to be pretty significant, a ten degree phase angle away from purely resistive. As Owen posted, it's so easy these days to deal with complex numbers that you may as well just carry them all along. Given the above formula, it's easy to figure the complex Zo for a line where you know the nominal attenuation, the velocity factor, and the frequency, and of course the nominal high frequency Zo value.

Cheers,
Tom

Richard,
It is well known that near maximum "overall" polarity gain can be
obtained by placing a vertical at right angles with respect to earth.
Now -a -days maximum gain is required of a certain polarity which
requires a specific accuracy of less than 1 degree . So yes, in your
working years straight up is good enough but these days of WiFi and
all that concentration is applied for purity of polarity which
requires a resonance at around 3 degrees to the vertical. This can be
determined arithematically according to known laws. Ofcourse as one
moves higher this offset angle changes. This same phenomina or tilt
angle applies for all polarities where maximum gain is required for
purity of polarization.The days have gone where just putting up a wire
satisfies all.
Regards
Art

Others have posted, correctly, that the propagation velocity is slower in some mediums than in others. I think it's a mistake, though, to say that c changes! c is supposed to be a constant, the speed of electromagnetic wave propagation in a vacuum--in fact, I suppose, in a vacuum with no gravitational fields in it. A description of fields in an electromagnetic wave often used the permittivity, epsilon, and permeability, mu, of the medium through which the wave is travelling. If it's through a vacuum, the values of epsilon and mu have values that are used often and have special notation--epsilon-sub-zero and mu-sub-zero. For convenience here, call them eo and uo. Then note that eo*uo = 1/c^2. As you might suspect, the propagation in a medium with larger values of e and u than eo and uo is slower than c. In fact, it should be velocity = sqrt(1/(e*u)).

Note that e has the units of capacitance/length -- commonly farads/meter -- and u has the units of inductance/length -- commonly henries/meter. But a farad is an ampere*second/volt, and a henry is a volt*second/amp, so the units of sqrt(1/(e*u)) are sqrt(1/((A*sec/V*meter)*(V*sec/A*meter))) = sqrt(meter^2/sec^2) = meters/sec. A unit analysis is often useful to insure you haven't made a mistake in your manipulation of equations.

So...in summary, c = f*w is actually not quite correct. It should be wave_velocity = f*w. c should be reserved to mean only the speed of light in a vacuum. If you're in a non-vacuum medium, and measure very accurately, you'll measure the same frequency, but a shorter wavelength: the wave doesn't travel as far to push a cycle past you, as compared with in vacuum. It's going slower.

If the propagation medium is, for example, solid polyethylene (the dielectric of most inexpensive coax cable), you'll find that w is about 0.66 times as much as it is in a vacuum, and the propagation velocity is similarly 0.66*c.

Cheers,
Tom

Hello,

I am just trying to get an updated list of the top brands of RG-6 quad shield coax cable. I have seen posts from a few years back mentioning Belden, Carol, and Commscope, but I just wanted to get an updated list. I have seen Carol and Zenith brands at local stores recently, are these any good? Mainly going to use this cable for running feeds from HDTV & analog TV antennas in the walls of a house.

Thank you very much for all feedback,
--
Chris

>
> Walt

Stealth, Walt. Stealth. Or--backpacking. Hey, it's less than 3dB loss. In any event, please note that Zo is independent of length. It's the same for a 3-foot length of line as for a 10000-foot length, assuming the line is indeed reasonably uniform. The A100 value is in the formula only because it's so easy to look up that value directly.

Interestingly, the attenuation of RG174 (because of the thin copper on the copperweld inner conductor) is relatively constant with frequency. It doesn't follow the same dB-proportional_to-sqrt(f) law of line with copper or tinned copper center conductor, at HF frequencies. So a 30 foot length of it is certainly fine for feedline to a receiving antenna at HF, and a very acceptable compromise for many people for foot-transportable or hidden-from-the-neighbors transmitting work.

Cheers,
Tom

Walter
Gain is the total radiation at a particular angle which can be the summation of all polarities such as in the case of vertical and horizontal antennas.
If one want's maximum gain with a particular polarization in mind then resonance is to be found at an angle other than 90 degree multiples to the earths surface. This is why I have made the point for years that the yagi has put antennas back nearly 100 years. In amateur work it is not so important tho it does explain why the augument rages between a yagi and a quad with the latter providing a much larger arrival area that allow people to hear more. On top of that the yagi becomes less efficient as one adds elements which means progressive polarity inaccuracy for each added element not only for a particular polarity but also for the increase in reactance for the array as a whole. I have mentioned 3 degrees but that was only by the eye on print out for a single element. I never did associate the tip angle with respect to frequency and height tho I am sure this can be done via Matlab for both a single element or an arrangement of elements.
One day they will put this in a book, hopefully the ARRL editions, so the derogatory statements from the older education type guys will cease but I am to old to see that day
Regards
Art

That's when you go to a Polish wedding and put on weight from eating kielbasa.

This is related to the "purity of polarization" which is a measure of the quality of the kielbasa served and the Polish music played at the wedding.

Owen's transmission line calculator gives the Z0 of RG-174
as 50.13-j3.59 at 1.8 MHz. That's an X0/R0 ratio of about
0.07, not 0.18.

Thank you everyone! I have a better understanding now. I guess part of my confusion is that on the same chapter thay have a table on the electromagnetic spectrum. In it, they list Radio Waves as having frquencies between 10kHz to 300Ghz and wavelengths of 30,000km to 1mm (I guess the 30,000 km is a typo in the book). Are these wavelength values based in a vacuum then?

3702. Distance Between Verticals??

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-05 18:34:41 UTC
From: Brian Kelly <kelly@dvol.com>
Message-ID: <1175798081.079004.288200@q75g2000hsh.googlegroups.com>
Source record: 43618

I'm putting up a bunch of HF and VHF verticals on a small property.
Couple questions: (1) Assume a 100W HF xcvr is used with ground-
mounted vertical HF dipoles and a 50W 2M mobile xcvr is used with a
gain-type vertical at say 30ft. How much separation (feet) between the
HF antennas and the 2M antenna should I have so that I don't fry the
front ends of either radio?

(2) Phase two of this project will be installing a 2M halo. How much
separation should I have between the halo and the vertical with
respect to acceptable interaction between the two antennas?

Thanks,
Brian w3rv

> is commonly considered.

I was considering the possible situation that a strike would have hit my
neighbor's house, as it is higher than mine, but since the well-grounded
tower was there it would take the hit instead, but still damage their
TV, etc. due to the induced currents in the area, and they might blame
me for their losses (since the strike hit my tower) even though the tower
might have saved them from a direct hit.
From the responses it looks like I'm probably over-concerned.

Hi Tom -

That's certainly one way to look at it. (Though it is a little like saying there is only one speed of sound.) Another way is to say that c = 1/root(mu*epsilon) for any media. Light does after all, always travel at the speed of light. ;-) Besides, it's more difficult to explain Cherenkov radiation without the expression 'faster than the speed of light in that medium'.

I thoroughly enjoyed the discussion you and Owen were (are) having regarding amplifiers.
Thank you for that.

Just do not worry about the cable; put 1/2" or preferably 3/4" ducts in the
walls.

Never place RF (or any) cable directly in concrete or masonry. If, for some
reason, you end up with a bad cable (soaked with rain water for instance)
you just have to pull it out and replace it. So you don't really need to go
for top brands and overrated and expensive cables.

If you intend to place short stretches (less than 10 or 15 meters) for the
VHF range, use RG6 with solid polyethylene dielectric. If you have to place
important lengths for UHF of satellite MF bands, use RG11 with polystyrene
or foam dielectric. I used train loads of Commscope cable without to many
problems. They gave weird names to their cables like 6ST??? for RG6 type and
11ST??? for RG11. Always use RF cable with copper clad core as they work
best with F type connectors. Stay away from jacketted cables with "flooding
compoud", even for underground placement.

Hi Jim,

Some people may use only c-sub-zero for the speed of light in a vacuum, but most commonly I see it simply as c, a fundamental physical constant. To avoid confusion, I would HIGHLY recommend that either you be very explicit that you're using co as the constant, and c as the speed of light in whatever medium you're dealing with -- OR that you're using c as the constant and whatever other notation for the speed elsewhere.

NIST lists the constant both ways: c, c-sub-zero. SEVERAL other places I just looked (reference books from my bookshelf; a web survey including US, UK and European sites--mostly physics sites; several university sites) only used c as the constant, except the NIST site and one other, which both listed it as c or c-sub-zero with equal weight.

It's clearly a matter only of notation, but I'll elect to stay with the most commonly used notation, and from what I've seen just now, most think c is a constant.

Cheers,
Tom

Clearly, the definition for the frequency range is somewhat
arbitrary. The boundary between infra-red and radio waves will
probably continue to be blurred as electronics advances further.

Radio waves down to much lower frequencies than 10kHz have been
used...the longer wavelengths penetrate water further, and are useful
for communicating with submarines. So don't be surprised if you come
across references to radio signals at 50Hz or so. Because
communications with radio waves is almost always based on propagation
through the vacuum of space, or through air which is only very
slightly slower, yes, the values for wavelength are based on c being a
constant, the speed of light in a vacuum.

Once you figure out one wavelength-frequency relationship, decade
(power-of-ten) values are easy:

1MHz = 300 meters (actually 299.792458, but almost universally taken
to be 300...)
10MHz = 30 meters
100MHz = 3 meters
etc...

Cheers,
Tom

Hi Tom -

This is becoming circuitous. What you're saying is exactly what led
the original correspondent to be confused in the first place. Since
the relavant equation doesn't read c = f*w/n, the only way to explain
the phenomenon is by using a value of c that varies with medium. That
was the entire point.

That's why I put it in quotes - to signify an unusual notation.

Yes. And it's very, very nearly the same for air.

The 30,000 km would be a typo -- the wavelength in a vacuum at 10 kHz
would be 30 km.

Art wrote:
"I have mentioned 3 degrees but that was only by eye on print out for a single element."

I have set the vertical angle of many highly directional dish feed horns using a bubble level when the path was long. The best setting will be horizontal so that the signal skims the earth when there are no obstructions.

Never did subsequent adjustment of elevation angle for best signal ever alter the bubble setting by one iota.

Why vertical or horizontal? To get the antennas parallel to each other. That`s why.

All electrical charges exert forces on one another. At great distances, the forces become vanishingly small. Even so, every effective antenna is coupled to other conducting matter in its rdiation path to do work in maintaining periodic motion of charges, however faint, throughout the universe. Energy transferred by an antenna to the universe is said to be radiated.

Radiation reflected by the ionosphere surrounding the earth is found to be scrambled in its polarization (the direction of its E-field).

Energy directly communicated between line-of-sight antennas is most effective when the transmitting and receiving antenna conductors are parallel. Conversely, when they are cross-polarized, loss may exceed 20 dB.

Best regards, Richard Harrison, KB5WZI

3713. Best beam for WARC?

Source record: 43528

Hi,

I have used a Butternut HF-9VX vertical for many years. Now I am thinking of getting a HF beam antenna. I am not into contesting. Rather I enjoy memorable QSO's with hams that like to share thoughts and ideas. Since I have enjoyed "local" (i.e. mostly Europe) QSO's with my vertical, I would now like to reach as far as I can, i.e. real DX's. I am doing CW and SSB equally much.

My interest profile leads me to optimize my beam for a warc band, on a higher frequency, e.g. 12m or 17meters. But how common is warc out there? If I got a 12 or 17meter mono bander, would I sit in vain to find the QSO's I want? Would it be more safe to just optimize for 20 meters?

Given the solar cycle I guess it would be wise to optimize for something in the "mid-range" wave lengths, like somewhere in the range of 17-20m, to be able to DX in the solar cycle dip as well. Is it a waist of money to get a beam for the higher frequencies, except during the high peaks in the solar cycle?

I would appreciate if anyone could share experiences and ideas on this matter. Also if some one could recommend a really good, high quality beam for my interest profile.

I make the loss/100' of RG174 to be 1.1dB and from that I get Xo=-3.6
ohms. (Did you get loss/100m from somewhere? This is probably the answer
to Cecil's diligent spot of an apparent error.)

> frequency, and of course the nominal high frequency Zo value.

Beyond dealing with transmission lines as Zo=Ro:

A common approximation for Xo is -Ro*alpha/beta and Ro=Ro. This
effectively (approximately) attributes all of the effect of the R element
of and RLGC model to Xo. Tom, your method is equivalent to this when
attenuation is converted to nepers/unit-length and frequency is converted
to radians/unit-length.

My line loss calculator at http://www.vk1od.net/tl/tllc.php takes a
different approach. It computes an estimate of the complex characteristic
impedance implied by the loss=k1*f^0.5+k2*f model, nominal Ro, and
velocity factor using an RLGC model. The model assumes:
* R is proportional to square root of frequency;
* L is constant;
* G is proportional to frequency; and

* C is constant.
These are reasonable assumptions for most practical transmission lines down to about 100kHz. The assumption to become invalid first is the first assumption (are you still with me) which depends of fully developed skin effect, hence the low frequency qualification.

The k1 and k2 values are obtained by regression from published attenuation figures.

I haven't seen this done in other calculators, so it is one of the reasons why my calculator will give slightly different results to others such as TLDETAILS for example.

Tom, in view of your comment about skin effect not being well developed in RG174, I went to Belden's data sheet for 8216 (RG174 type) and sure enough, the loss below 30 MHZ does not track the loss=k1*f^0.5+k2*f model. Your loss figure of 2.7dB/100' may well be correct, and my line loss calculator is in error below 30MHz for this particular cable due to the thin copper plating and steel core of the inner conductor. TLDETAILS and other calculators based on the same loss model will also be in error. I note that the ARRL TLW shows 1.8dB/100' for 8216 at 1.8MHz.

This sets me thinking of a way to calculate a lower frequency limit to the loss model when I generate it, so that I can store that limit in the database and prevent calculation below that frequency.

No Richard, you are out of date.I'm sure that more about antennas is
taught
these days that has never showed up in Terman. On the tipping thing
many towers have multiple beamms on them and when one is added then
owners have to reset their antennas. Now ofcourse one can now move
them remotely until max polarity is observed. As far as parallel is
concerned, anytime you introduce reactance to the resonance to an
individual element you lose out on efficiency if polarity is a concern
qand in Termans time polarity was not that much of a concern. I truly
believe that most auguments on this newsgroup is because teachings of

yesteryear do not match up to present day teachings. With weather forcasters they now direct R.F at a front first with horizontal polarization and then with vertical polarization and then merge the reflected pictures, thus it is imperitivethat polarization is dead on for 3 D analysis of the weather front. Lots of things are done these days that wasn't even thought about as little as 20 years ago such that you must read iee antenna findings every month to keep up.

My experience with a few Carol Cable products (including coax) has been
good. I would consider that the Zenith brand name appears to be rented
out to the best bidder these days (peruse a.h.r for recent stories about
Heath/Zenith products) and expect that the manufacturer spent most of the
cost of making that coax on the marketing of that coax.

I have just analysed the tllc database contents to find cases where the
modelled error is more than 10% different to the data points on which the
regression was based.

There are a few cases, they are all copper clad steel inner conductors
(some of the RG6, RG59, RG174, RG316). I need to implement a lower
frequency limit for model validity for each cable type.

An alternative approach to retain some lower frequency results is to use a
cubic spline interpolation... but it has its own problems.

Owen

Belden 1694A is a nice cable, as is Canare L-5CFB.

I built a component cable set for my front projector out of the Canare V3-5CFB, which is basically similar to the L-5CFB but has three cables wrapped together in a single jacket. Works very well.

Walt, if you are looking for maximum horizontal or any other polarity
it can only be obtained by removal of reception of other polarities,
this maximum is obtained by having the radiator at <90 degree
multiples with respect to earth. You can prove this to your self
anytime by calculating max horizontal gain by progressively tipping a
dipole while keeping it resonant until the maximum is reached. If your
concern is for total gain without regard to polarity mix then the
vertical position total gain will equal the total gain of the tipped
dipole. The difference is that one arrangement has a mixture of
polarities where-as the tipped antenna will only provide a single
polarity. If another element or anything else is added near enough to
add reactance then the prior antenna must be adjusted to remove it,
thus the reason for remote adjustment which is much cheaper to
maintain rather than regular trips up a tower by maintanance men.
Hopefully Walter this will bring you up to date. I have no reason for
a 300 posting thread as I do not intend to write rev 3 of Reflections
or anything else.

But since it leads to a contradiction as far as energy
goes, it must be in error. The raging inferno that is
the source is apparently not transparent to waves traveling
in the opposite direction.

Good evening, Bryan.

Thanks, but there are a couple of problems... the antenna will be for 160 through 40 and so two of the traps will be for 80 meters... I forget what the capacitance will be but I think it was somewhere in the 200 pf range. Also, the antenna is meant to be portable, and so the traps need to be as physically small as practical. Also the power will usually be low... as low as 5 watts, usually no more than 50 and never more than 100 watts... so I guess I need to make the antenna as efficient as I can... kind of a contradiction in terms for trapped antennas especially where the traps need to be physically small.

If I could find the doorknob capacitors for a reasonable price that would be ideal, but $15 each is way too much.

On the other hand, the ones from RF Parts are all at least 4 KV, and up from there (40-50 KV). I don't know how to accurately calculate the voltage rating I'll need (I'll post that as another question under another topic), but my guess is that for 100 watts max, I don't need 5 KV, and may not need 1 KV.

Who else besides RF Parts has these things and has a decent website?

3729. Calculating trap capacitor voltage rating

Newsgroup: rec.radio.amateur.antenna

Source record: 43545

How do I calculate the voltage rating I'll need for capacitors used to make traps?

I am making a portable field antenna for 160 through 40 meters, for use with 100 watts absolute maximum (normal use will be from 5 to 50 watts).

Hi Owen,

Yes, I've played with the same model (k1*sqrt(f)+k2*f) for loss. For
things below 500MHz or so--and generally above--the k2 term seemed to
always be so low as to not be worth including. For one thing, the
high-frequency apparent loss may well NOT be due to increased loss in
the dielectric, but rather to variations in impedance along the line
or some similar phenomenon. Published specs for precision lines seem
to be a lot closer than those for "garden variety coax" to what I'd
expect based on theory and what I believe to be the dielectric's power
factor for polyethylene and PTFE. Assuming that all types of line
from a given reputable manufacturer use the same quality polyethylene
and the same quality PTFE, we should see the same contribution from
dielectric, taking into account solid versus foam, for all types: at
a given frequency, the dielectric loss of the poly or PTFE should be
the same. If that's the case, then for some lines at least, the k2
factor must not be due entirely to dielectric loss.

A note on my simple formula: one of the approximations in it is that the phase angle of Zo is assumed to be close to zero, so that sqrt(1+j*x) can be reasonably approximated as 1+j*x/2. For x=+/- 0.2, the error magnitude is less than 0.005, and the error in the imaginary part is less than 0.0005. But for line that has a seriously reactive Zo, the error can be large.

We have Roy to thank for pointing out to me, several years ago, that characteristic of RG-174. I knew I'd have a chance to thank him in public for it sometime. ;-)

Cheers,
Tom

Sorry Richard, my surgery had to be postponed a second time, first, to wait after my cataract surgery, and
second, just before the procedure was to be performed, my dentist discovered an infected tooth. One of its
roots was cracked, and I spent one heluva night last night after having the root removed. Consequently, my
spinal surgery has been moved to April 18. This is gettin' ridiculous! But thanks for your concern.

Walt

It should be easy to prove. Hook up two IC-706's in
series driving a 50 ohm dummy load. Install some
feedback to make them coherent. Turn one off and
one on. Then turn the other off and the other on.
Then turn them both on. Do they satisfy the
principle of superposition?

Art, using correct terminology is essential in preventing misunderstandings, as you have done with 'polarity'.
You have confused 'polarity' with 'polarization'--the two are not synonomous, but are distinctly different.

Sorry, Art, your misuse of this term has been confusing, rather than enlightening. Are you blaming me for the
more than 300 postings on this thread?

Walt

Walt
Now why would I blame you for over 300 postings? Obviously you have created some confusion which is natural for our hobby since we are an old group which gives justification to "there is no fool like an old fool" Nothing personal. Lets face it we oversell experience when in a lot of cases it is the same experience over and over again. Anybody here who remembers the Sputnik probably would not be able to get a degree today or even the same job. On this tilt thing if you look at patents in the 6 million plus area most would not understand what they were referring to, whereas the present day student understands thing fully since he grew up with digital transmissions. Heck most of us retired before the last ten years which is becoming the heydays of antenna research. Yes, as I get older I make the same mistakes as all old people do and you make provision for other old people unless you think your self as perfect as would a younger person who just got his degree and was up to date.
The difference ofcourse is the young student wants to prove things to himself until he gets behind technically when he then asks for proof from others. If I look back at the past arguments on my threads many pull out the 50 year old books that we have stored away. The modern student will look up Google and even if he is a few years out of school would have checked the computor for reference to "adjusting antennas" or "tilting antennas"to get up to date where as the old timer thinks he is still back in the old days so his knoweledge is up to date and cannot adapt to the present situation he there is no reference to that in my books.Odd thing I saw the other day was a book by Terman and would you believe it nowhere in the book does the words of "maxwell" or Gauss" show up so they must be imaginary also. Yup, Walt as you get older you will find that a lot more people are mixed up except you and need to be told so until the time come that more people are saying it to you forcing you to be more tolerant.
Frankly a lot of people on this net need to get up to speed with respect to radiation such as tipped antennas e.t.c instead of discarding information in
favour of the opportunity to mock while the younger more knowledgable members give a quiet smile to themselves. Walt were you aware of the reasons for tipping? I doubt it because you probably can remember the Sputnik when the standards of education was lower and Google was not around.
Never heard you come forward with respect to the Gaussian and Maxwell argument either before or after the young M.I.T guy put every body straight or did you know it anyway but just didn't want to correct

people then?

One way to put an absolute maximum rating on the trap voltage and current is to assume that ALL your power is dissipated in the trap. Obviously, that would be a real bummer, but it's a limit. In the case of a symmetric dipole, the power would divide, probably fairly close to equally, between the two sides. Remember that you want to be sure the cap doesn't flash over, so take into account peak voltages: peaks of modulation, etc.

So if you have a trap that, at resonance, has Xc=Xl, and has some Q, then at power P dissipated in the trap, the voltage will be sqrt(Xl*Q*P). Circulating current will be sqrt(P*Q/Xl). You mentioned in another posting 100 watts absolute max, and 200pF resonant at 80 meters, so Xc=Xl=200 ohms, approximately. You want to make them small, so I'd guess Q<300...let's say Q=200. So for the case of 100W in one trap (that coil's gonna get really hot if it really is required to dissipate that for long...), that's Vrms=sqrt(200*200*100)=2000V. Irms=sqrt(100*200/200)=10A. Please note that the CURRENT in the cap may be a bigger problem than the voltage across it!

That's absolute worst-case. I'd guess you'll see more like 5 watts max per side dissipated with 100 watts input, the rest being radiated, and if that is indeed the case, Vrms=450V and Irms=2.23A. If there's only 1 watt dissipated, it's still 200V and 1A.

At about 30pF/foot, RG-58 could do the job, but 200pF would be almost 7 feet of coax. That would be economical, to be sure, and should be up to the job with no problems. Paralleling some high voltage ceramic discs would probably work...use NPO (C0G) type, maybe 5 or 10 in parallel to avoid current problems.

Cheers,
Tom

I don't know of any general way to calculate it, but you can easily get the data from a model. In EZNEC, clicking Load Dat will show you the voltage across and current through a "load" (in this case, trap), as well as its power loss. Other programs have an equivalent feature.

Hi Jim,

OK, but I still say that, in that case, the equation (c=f*w) uses c in
a way that's inconsistent with common usage of c. I don't know if the
article quoted by the OP mentions that, or if somewhere it adds other
qualification, but if it's not out of context, then it would confuse
me, too, if I were trying to understand it for the first time. At the
very least, the article should say somewhere that c is the speed of
propagation in whatever medium we're dealing with, and if it did,

perhaps the OP wouldn't have been confused about it in the first place. His posting makes it very clear to me that HE thought c was a constant, as I would if the author didn't tell me otherwise.

Cheers,
Tom

The antenna can be designed so that traps are not resonant at the operating frequency, and that tends to reduce the voltage impressed across the traps.

Modelling might give you the best indication of the operating voltage on the traps. Don't forget to allow for peak and a safety margin.

Another approach is the so called coax trap. I have seen many descriptions of these things, and they are all different, so I thought I would write my own which, in keeping with the others, is also different. My approach was to describe them using a transmission line explanation. Such an explanation suggests they are a lot better than at first might meet the eye. My notes are at http://www.vk1od.net/coaxtrap/index.htm .

Owen,
the laws are different in Australia. In the U.S. laws are made first
without a ruling what the the actual "words" inferred where as
"intent" of the law in Australia and other places is of prime
importance. As time passes by words uttered can change their meaning
from the original intent thus solutions can be delayed for years where
nothing is really final. Also in the U.S. anybody can sue anybody and
with impunity where as in other countries the loser pays the costs of
the court action.In America the person with the most money nearly
always wins and the poor finish up in jail since each side pays his
own costs and only gets the attorney that he can afford before his
money runs out.You can even get away with murder here
if you have deep pockets and in a lot of cases charges will be dropped
or diminished if the County does not have enough money to pursue a
lengthy trial where you must bear in mind that the opportunity for
unlimited appeals depend on the depth of the pocket of the
accused.America is broke
financially and in a lot of cases criminals are not arrested or let
out of prison early to make room for new entrants! We tried to make an
Empire without sufficient money on hand and thus we lost a Country.

Belden, Alpha and Carol are all good. As important as the cable are
the connectors. The compression type are the way to go, IMO. Invest
in a good QS stripper and a compression tool. Don't bother with crimp
tools and don't even think about twist-on.

Art, you say I have created confusion? Over what? Confusion? How about responding to your misuse of the term
'polarity'? Now that's confusion.

And you say that some MIT guy put everybody straight? Just what is it the everybody needed straightening about
that the MIT guy is supposed to have done? And are you implying that Terman, Kraus, Johnson, et al are wrong,
and that we need 'straightening out' because we learned it wrong from these masters of 50

years ago?

And you're also saying that our educational standards are better now? Art, what have you been smoking? And are
you also saying that the new graduate with no hands-on experience outweighs a graduate of 30 years ago with
experience gained during those 30 years? What planet are you from, Art, certainly not Earth.

Think about it,

Walt, W2DU

> Obviously, if any system conditions change when power is
> applied the basic rules for the superposition principle
> have been violated.

Firstly, the principle of conservation of energy always holds.
I don't think anyone has ever disputed that.

Secondly, about superposition. A sufficient condition for
superposition to hold is that all the components are linear
and time-invariant. Examining the ideal transmission lines
used in our simple examples, this is true and superposition
holds on the transmission line. This is also true for the
components in our simple generators so superposition holds
there as well. And it holds for the system consisting of the
generator and the transmission line.

But as I understand, you have done some analysis which brings
superposition into conflict with conservation of energy and
you have concluded that one of them must be wrong. (And having
had strong success with conservation of energy, you have
chosen superposition to be wrong.)

But there is a third choice. Perhaps there is an error in the
way that you have connected the dots between superposition
and conservation of energy. Perhaps, as a result, superposition
and conservation of energy are not in conflict at all.

And this is indeed the case. Since both are true, the error must
be in how the dots are connected.

I suggest you carefully examine the chain of logic that causes you to conclude that they disagree. That is the path to resolving the contradiction.

If you would care to lay out the chain that connects the dots, I would be happy to attempt to help with locating the misstep.

...Keith

I've asked Richard how to hook up two IC-706's in
series to get them to meet the requirements of
the superposition principle. Maybe you can show
us how to do it.

Hi Rick,

As Owen mentioned, a single coaxial stub would likely be physically unwieldy. IIRC, I used a short stub as a padder across a doorknob capacitor (tuned to 40m). Certainly, coaxial cable used as a capacitor won't be as good as a ceramic or porcelain capacitor but, my trap dipole worked fine for me. Another common idea is to use a coaxial trap. It's worth investigating, and inexpensive to try.

The company I work for uses a lot of porcelain dielectric capacitors (a VERY good hi-Q/low ESR dielectric) from American Technical Ceramics (http://www.atceramics.com/). Look at ATC's "multilayer capacitor" line. They're physically small and, if chosen properly, will handle higher voltages and currents.

For ceramic and mica transmitting capacitors, you might try the surplus vendors. A few are:
Fair Radio Sales (http://www.fairradio.com/)
Surplus Sales of Nebraska (http://www.surplussales.com/)
All-Tronics (http://www.alltronics.com/)
Economy Electronics (http://www.economyelectronics.com/)
Ocean State Electronics (http://www.oselectronics.com/)

Another possible resource is FaradNet (http://www.faradnet.com/).

Hi Paul

What is the problem with "twist-ons"? I dont question your judgement,
but I have found them to be good for my 2 meter application.

Now I am considering doing some work at 2 GHz. This is a good time for me
to learn about cable and F connectors.

Thanks
Jerry

Walter, you complained about not getting as many responses as I, I
accept that sometimes my threads are as long as 50 posts instead of
just a few for agreement Yours is now >300 is it you or others who are
confused.You think about it

Confusion? How about responding to your misuse of the term
> 'polarity'? Now that's confusion.
>
> And you say that some MIT guy put everybody straight? Just what is it the everybody
needed straightening about
> that the MIT guy is supposed to have done?
Well one person finally concurred and nobody refuted this concurrence
so you think the majority are correct because they didn't agree?

And are you implying that Terman, Kraus, Johnson, et al are wrong,
> and that we need 'straightening out' because we learned it wrong from these masters of 50
years ago?
You remembered it from 50 years ago, that is a lot of difference from
truly understanding it. The MIT and another individual from down under
agreed with the mathematics that underlined what I was talking about
invoking what the masters stated. So it is you who must have learned
it wrong 50 years ago
but you have time to correct the M.I.T guy and the guy from down under
that they had misused mathematics some how and came up with formular
that disputes the masters. Actually the guy from MIT gave a terrific
response that didnot receive any reject from anybody including you.
>
> And you're also saying that our educational standards are better now? Art, what have you
been smoking? And are
> you also saying that the new graduate with no hands-on experience outweighs a graduate of
30 years ago with
> experience gained during those 30 years?

Yes I do unless the experienced guy kept up with progress such as a
Professor. When I spoke about polarity and tipping a younger person
knowing what I was talking about would have adapted while you who knew
nothing about the subject could not adapt. If you are not aware of
modern day practices then you would not get hired today. New graduates
always get the nod over senior citizens.

What planet are you from, Art, certainly not Earth.

It is on earth we are talking about when we talk of tilting and the
correlattion of gaussian theory with respect to radiation. You have
presented nothing with respect to supposed inaccuracy which says you
are ignorant of it. Why else does one ridicule another person by
moving away from science ? So if you disagree with the tipping process
for antennas or if you disagree with the response from M.I.T. then put
your stake in the ground and state your superiority in mathematacs
rather than driving the stake into the messenger. If you take this
small step I assure you this thread will not last as long as yours.
You may be able to distort science
but you can't refute mathematics by killing the mathematician. Perhaps

it is better that you put your eyes and ears back into the ground . On
the other hand I would be impressed if you could prove your position
but you have shown that you can't by burying your head in the sand.
Walter we are all getting older and it is harder to keep up with
things, that is something that we all have to accept and you are not
immune to it, and it shows
Art

Hi Tom,

The speed of light is always constant - within its frame of reference.
It is only for those that inhabit a different frame that it "appears"
to be different. By Lorentzian laws, there is no time at the speed of
light and everything is simultaneous - source and load are
inseparable.

To illustrate at a slightly slower speed (from Feynman):
"A very interesting example of the slowing of time with motion
is furnished mu-mesons (muons), which are particles that
disintegrate spontaneously after an average lifetime of 2.2 ï¿½S.
They come to earth in cosmic rays.... It is clear that in its
short lifetime a muon cannot travel, even at the speed of light,
much more than 600 meters. But although the muons are created at
the top of the atmosphere, some 10 kilometers up, yet they are
actually found in a laboratory down here, in cosmic rays. How can
that be? The answer is that .... While from OUR own point of view
they live considerably longer ... time is increased ... by
1/SQRT(1-(uï¿½/vï¿½))."

Two reasons I don't like twist-ons. First, I don't find them to make
that great of a mechanical connection and can therefore be pulled off
the cable fairly easily.

Second, and I admit I don't have network analyzer plots to back this
up or anything, I've always found them to make a mess of the shields
when you twist them. That could lead to more of an impedance bump at
the connector than with other types. Probably not an issue at 2
meters, but more important as the frequency goes up.

Sure, but I thought it would be obvious that there are many
ways, but take the following as an example.

Place them side by side on the bench.
Take a piece of coax sufficiently long to reach between the
output jacks.
Put an appropriate plug on each end of the coax.
Plug the plugs into the output jacks.

...Keith

PS. Was there a real question there somewhere?
What outcome were you expecting to observe?

And there will be no progress until you explain why you think
that superposition and conservation of energy are in conflict.
You have, for years, claimed that conservation of energy holds,
a claim with which there is general agreement.
Only a week ago you started a thread to argue that superposition
holds, another claim with which there is general agreement.
And yet suddenly you are prepared to discard superposition.
Do you not think it worthwhile to examine the reasons to ensure
that you are not making a mistake?
After all, superposition is a powerful technique and none of the
text books mention special caveats that constrain how it can
be applied to generators.
Where is the source of your conflict?

Good morning, Bryan.

I have done some reading on coax traps, and consulted with some who, as the old saying goes, have probably forgotten more than I will ever know about antennas, and I'm told they tend to be fairly lossy and inefficient. They are certainly easier and cheaper to build than the coil-and-capacitor type. The big thing that concerns me about coax traps is that they need to be fairly small and portable, meaning I'd probably make them out of RG-58, and I wondered if RG-58 or even RG-8X would handle the voltage.

> For ceramic and mica transmitting capacitors, you might try the surplus

Thanks. Fair Radio looks like they have a pretty good selection.

In order to satisfy the results predicted by superposition,
I don't see how you can double the voltage by putting
them in parallel. That's why I asked you to put them
in series. Please put them is series such that the
two component voltages are doubled and the two component
currents are doubled when both transmitters are powered
on.

Also please tell us how the powered-down transmitter
handles the voltage and current that it is exposed
to when the other transmitter is powered up. I
seriously doubt your implication that it is a linear
process.

> PS. Was there a real question there somewhere?
> What outcome were you expecting to observe?

I am expecting the signal from the powered-on
transmitter not to make it through the circuitry
of the powered-down transmitter. I am expecting
smoke when you try to superpose two coherent 100w
signals into a single 400w signal.

> And there will be no progress until you explain why you think
> that superposition and conservation of energy are in conflict.

There's a name for people who try to tell others what
they think. I do not think there is a conflict and am
absolutely NOT asserting that the conservation of energy
principle and the superposition *principles* are in
conflict. Such is a figment of your imagination. Please
listen closely:

THE AVERAGE AMATEUR RADIO TRANSMITTER DOES NOT MEET
THE RULES NECESSARY FOR THE SUPERPOSITION PRINCIPLE
TO APPLY! Got it?

There's nothing wrong with the superposition principle.
It simply doesn't apply to certain circuits including
the average commercial amateur radio transmitter.

While the connector thread will crush the outer somewhat (causing a very
short piece of low Zo), it's unlikely to be a problem in most
applications, even at 2GHz.

Ian.

What's the diff between a compression tool and a crimp tool?

OT: I inherited break/fix responsibility (billable by the hour) on a
business thinwire lan that was installed by a TV cable guy. He used
twist-ons and no crimp rings. That site paid my rent for a couple
years, until I eventually replaced all the connectors with proper
ends.

For that reason, I've always looked fondly on twist-ons, in a bizzare
way.

I'm just guessing but it would be tough to go into court and prove the actions of a bolt of lightning that may or may not have been attracted by your tower and then skipped to your neighbor's property and did damage.

Where would the proof be on a bolt of lightning that lasted less than a second and likely had no witnesses?

If your tower is up to spec on grounding paraphernalia, you ought to be okay.

What are the common issues with the crimp-on connectors? I've been
using them here and there mainly because they are cheap. So far I
haven't really noticed any problems, but maybe it's because I haven't
used anything else to see an improvement. Thanks!!

it not that they are so bad it just that the compression fittings are the
way to go.

Heh Jimmie,
I was looking at a book that showed the scanning lines of a tv.
It also showed aperture as being bisected equally by these same
scanning lines.
Since aperture is directly related to gain one could probably state
that the
angle of the scan lines on a TV is directly related to the tipping
angle for radiation. Both are magnetically related ie angle of release
of an electron so you may get a better answer from a T.V. technician
with respect to angles than ham radio operators. Isn't science great
when your brain is nimble and curious!

The compression fitting have a captive sleeve on the cable end of the
fitting. You strip the cable more or less as usual, slide it up
through the connector as you would with a crimp type. But then the
compression tool presses the sleeve up into the body of the connector.
The inside is tapered, so when the sleeve is pressed in, it compresses
against the cable, locking it tightly into place.

Here's a picture:

http://www.cablestogo.com/product.asp?cat%5Fid=411&sku=41077

They are also available with seals for water resistant outdoor use.
(In fact, the picture is of a connector with seals.)

Here's what the tool looks like:

http://www.cablestogo.com/product.asp?cat%5Fid=1403&sku=38011

Try 'em, you'll like 'em!

Twist-in connectors do not provide the shielding that a CATV system needs. They are a HUGE source of ingress/egress, and the return loss is rather low (the higher the better. Hex-crimp fittings have ~18dB, and compression are >30dB). Plus, It actually takes more time to put on a twist-on connector that it does to put on a real connector.

Compression fittings may cost a little more for the connector and the installation tools, but cost less in labor (time) to install. Not to mention the materials/time spent in replacing the twist-on connectors with real ones when they don't work properly.

OK. It's a large, well engineered crimp tool and fitting.

I actually have tools, some cable, and a bag of ends that fit that
description. I just considered them standard tools and parts for
serious work. They came to me by accident. I was the "customer" for a
a pre-ethernet LAN built on CATV plant that spanned a 40 floor
building.

Hex-crimp fittings have 6 points where the connector is pinched into the cable creating small impedance mismatches. Impedance mismatch creates reflection. If the reflection(s) is(are) severe enough, whatever is at that(those) frequency (frequencies) may not work. Plus, their return loss is a fair amount lower than that of compression connectors (~18dB as compared to >30dB).

I've replaced hex-crimp fittings on DirecTV systems because of hex-crimp fittings which were causing some channels to not work.

Go to http://www.cencom94.com/Download.html and check out DBS Tutorial. Pages 12 & 13 illustrates why you don't want to use hex-crimp fittings.

A couple of years ago the house took a lightning strike that I deduced
damaged cabling provided by the cable system(Time-Warner). I removed
my additions and placed a service call. When the truck arrived I
showed them where I had dropped my stuff off the system and restored
their original configuration. After they fixed the connector arc-overs
they ran there signal leakage test. Then they requested I restore my
alterations and one by one they chased down ALL of the twist-on and
crimp connections that I had made and replaced them with their own
compression fittings. The results were better picture quality, zero RF
influence from the Ham Xmtr, and higher speed Internet.

I think I better invest in the connectors and tool to keep things
tidy.

The 40-floor internal CATV system I was a customer of was very close
to, and LOS with the Empire State Building antennas. The cabling
engineers described the CATV system as one big antenna. Problems that
poped up tended to be a bad connector or a grounding problem. It wasa
data lan so if there was a problem we couldn't just tell theuser to
watch the ghosts until we got around to fixing it.

Hi Cecil -

There are examples of superposition in commercial equipment. Check out the QSC Audio web page. In particular note the specs on their stereo power amps in bridged mode.

Your expectation of obtaining 400 watts from two 100 watt radios hints at a possible error in your understanding regarding simultaneously superposing voltages and currents. Just a thought.

Art wrote:
"Frankly a lot of people on this net need to get up to speed with respect to radiation such as tipped antennas ---."

Yesterday`s response seems to have been gobbled in cyber space.

Not all my reference books are over 50 years old. One of my best was published in 2003 although its principal author was born in 1910. He is J.D. Kraus, but he had numerous and likely younger collaborators, 6 of whom are listed as co-authors. The title: "Antennas For All Applications. 3rd edition".

On page 297 is found an item which illustrates what happens when you tip an antenna. It is titled: "Antenna Rotation Experiments":
"Consider the radio circuit shown in Fig. 8-74a in which one antenna is circularly polarized (a turnstile?) and the other is linearly polarized. If one of the antennas is rotated about its axis a frequency f (r/s), the received signal is shifted to F + or - f, where F is the transmitter frequency."

Fig. 8-74 notes:
"Antenna rotation produces amplitude modulation."

Of course it does. When the linear antenna is aligned parallel to one axis of the CP antenna, the signal is maximum. When the linear antenna is most misaligned with either axis of the CP antenna, signal is a minimum. The example demonstrates why polarization alignment, not tipping or tilt, is usually important.

Best regards, Richard Harrison, KB5WZI

Not the least of which is that you (philosophically) want a model that
is based on the underlying physics (which the sqrt(f), f model is)..
The problem comes in because sqrt(f) doesn't model skin effect at low
frequencies very well, when the skin depth becomes an appreciable
fraction of the conductor diameter (because the conductor is no longer a
thin wall tube).. the cladding just throws another wrench into the works.

What might work is if you look at the generic curves for Rac/Rdc for
round and tubular conductors. The analytical formulation is quite
complex, but I'm pretty sure there's a simple polynomial approximation.

Seems to me you're way off point here, Richard. I'm in my lab, my inertial frame of reference. I send some EM waves through my vacuum chamber and I measure their speed as 2.997...*10^8 meters/second. The same waves continue on through the glass of the bell jar keeping air out of my vacuum, and I happen to notice that their speed through that glass is1.684*10^8 meters/second. I notice that light from my hydrogen light source contains certain well-defined spectral lines, but each of those passes through my vacuum at the same speed. However, I notice that those lines, in a short pulse of light, come out of the glass separated in time slightly, implying that they took different times to get through the glass, and were therefore not even travelling through the glass at the same velocity; I notice no such separation for the light passing through the vacuum. Further, I notice that light from a distant star has apparently the same set of

spectral lines, but they are shifted to slightly longer wavelengths. However, they take the same time to pass through the vacuum as my locally-generated hydrogen light. All my measurements are in the same frame of reference, and IN VACUUM the speed of em radiation appears from all my measurements to be the same, no matter its wavelength, even for very long wavelengths, but in other media, still the same inertial reference frame, it's different. I also happen to notice that the light from the distant star was created in a different inertial frame of reference...

OK, I'll shut up on this now.

Cheers,
Tom

> Who else besides RF Parts has these things and has a decent website?

I've bought a lot of HV capacitors for various applications over the
years, both surplus and new.

RF parts has fairly reasonable prices for new components. The actual
manufacturer Ceramite, is a division of Vishay. TDK also makes this
kind of capacitor. And, for surface mount, there are some high
current/high voltage RF capacitor manufacturers (ATC, Murata Erie,
Dielectric Labs). These things aren't made in huge volumes and they're
fairly expensive, brand new.

You might find surplus or used parts much cheaper (e.g. eBay)..
Something to watch out for.. there are two very different series of
"doorknob" style capacitors. One is used for DC kinds of applications
and can't handle much RF current (you used to see these as filter

capacitors in flyback type power supplies at 15.75 kHz). The other is designed for RF current. The ones that can handle current cost a LOT more.

And, if you're buying used... The failure/wearout mode with overvoltage is that the metalization on the ceramic gradually goes away, reducing the capacitance. The failure/wearout mode with overcurrent is microcracks in the ceramic dielectric from thermal stresses. The capacitance tends to be fairly constant (these aren't high precision devices anyway.. 20% is a close tolerance part), but they'll have a C that varies with voltage and temperature, and the breakdown voltage will decrease ("treeing in the dielectric").

Even the RF devices aren't intended for use in a tuned circuit.. they're used for DC blocks and RF bypassing, where the capacitance isn't critical. They often have a fairly large temperature coefficient, as well.

What you might want to look into is capacitors with very low ESR made for power converters. The Cornell Dubilier 942P or Wima FKP1 series, for instance. They use polypropylene dielectric with extended foil construction and 0.15 uF 2kV parts run a couple bucks. They're widely used in <1MHz power applications (and can be run at 2 or 3x their voltage ratings, if you want to be bold and thrifty). The key specs to look at are RMS rf current ratings (which are thermally limited, by the way)

If they aren't low loss enough (or you can't get them in small enough capacitance), you might look at paralleling or stacking SMT ceramic caps from the vendors above. 1kV parts are readily available. I have a 1kW 13 MHz power amp here that uses 11 pieces of a 56 pF cap in parallel in series with the RF and a half dozen 100pF 2.5kV units in shunt in the output network.

I will have to read it for myself, it doesn't seem to be relavent but
I'll check to see if you are seeing things in context. The book I
quoted regarding scan lines was Terman by the way. The Kraus book did
not present any great changes to older versions which is often the
case when publishers present 2nd or 3rd editions to squeeze any
remaining profits However I will read it to see if the microwave
portion is up to date rather than a reissue

Kind of depends on who's building your house. Conduit would be quite unusual in most residential construction, and would be likely very expensive. I suspect you could run 10 parallel runs of high quality RG-6 without conduit and still cost a lot less than the conduit. Just abandon a run if it fails. The labor for conduit installation (especially if they are not already installing it) is high..

In most houses, the wiring is done after the structure is built, and the electricians go through with a drill and spade bit and drill the studs to run the cables. They have the flexibility to run the cable anywhere convenient (for instance, around plumbing that is in the way).

You would want to remind the folks doing the installation that the standard is to keep low and high voltage separated by more than 12", and particularly (because it's not in the code) that you want decent bend radii. Otherwise, they tend to string the cable and just pull it snug, which will almost always bend it too tightly, particularly where they come down from the attic through the header at the top of a wall.

There are flexible (plastic) conduits available which are somewhat
easier to route, but still, you run into a problem with drilling lots of
1.5" holes (to clear the od of the conduit) in studs that are only
3.5" wide. The inspectors don't like to see it, especially if all the
holes are lined up in a straight line. To them it starts to look like
the edge of a perforated ticket stub saying "tear here".

You'll wonder how you ever did without them. Ebay is a great source
for compression fittings. Keyword Digicon. I got my first tool for
Thomas and Betts and the T&B system. When the fittings became pricey,
I switched to Digicons. Since I didn't want to convert my tool all
the time, I grabbed an LCCT tool and fittings. My guy in the Detroit
area (about 50 miles away) sells me a few hundred at a time. I paid
$108 with shipping for 300 the last time and had them in about 30
hours from the time I placed my order.

Put two 70.7 vdc batteries in series with a 50 ohm load.
Switch in one battery at a time. Each battery will
supply 100 watts. Now switch in both batteries. They
will supply a combined 400 watts. The batteries are
required to supply the extra constructive interference
energy assuming each battery maintains its constant
70.7 vdc voltage output.

This is what has to happen when two coherent RF voltages
are superposed in phase. I just don't think an IC-706
will do that, i.e. it is not a linear device, thus
violating the requirements for superposition. In phase
superposition would require that:

Vtot = V1/_0 deg + V2/_0 deg = |V1|+|V2|

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(0)

Ptot = 100w + 100w + 2*SQRT(100w*100w) = 400w

Presupposition of linearity of any amateur radio
transmitter without proof is foolish as is the
presupposition that a ten cent resistor or a $10
resistor will gobble up all the reflected energy.

If the tower is well grounded, and takes the strike to ground in a
orderly miltary manner, there should be no problems.
I've taken two strikes to my mast which is 15 feet away from
where I'm sitting, and I've had no problems at all. My puter
amd display didn't flinch, and there was no damage to anything
in the house. The tower ground is ultra critical in this regard.
It must be good, or the strike may decide it likes another route
to ground.

Funny how it works where a bad connector will blank out just a couple of
cable chanels. First time this hapened to me about 20 years ago the cable
guy came out and said it was a bad connection. Almost laughed at him,but he
replaced the connector at the outside of the house and it cleared right up.

Holy cow. Happy Good Friday by the way.

A 100 watt source is something which ostensibly produces a maximum of
70.7 volts and a maximum 1.414 amps into a 50 ohm load. There are two
ways to superpose the outputs of 100 watts sources such as this. One
way is to superpose voltages by arranging them in series. The total
output voltage available would then 141.4 volts. But doing so does
not allow the source to produce current beyond some limit. Maximum
current would still ostensibly be 1.414 amps. To increase the
available current one could arrange the sources in parallel and
basically 'superpose' the currents. However this does not increase
the available voltage. That is still ostensibly 70.7. volts. Total

current from the two sources in parallel into a 50 ohm load would now be 2.828 amps.

A car battery does not have a 100 watt limit, or in particular, a 1.414 amp limit. When you put two batteries in series you are more of less superposing the voltages, but you aren't superposing currents. Since the battery doesn't have a 1.414 amp current limit, the batteries can each now produce 141.4 volts divided by 50 ohms worth of current. Since they are arranged in series, each battery will produce 2.828 amps of current. It isn't a superposition thing. Put the batteries in parallel as a check on your notion of superposition.

Your numbers highlight the problem using irradiance equations with power terms in them. You're getting the wrong answer because power doesn't interfere, so it's pretty ridiculous to put it into an interference equation in the first place. Look at the risk you run doing it. There is nothing wrong with the proper use of superposition and interference. Given that, what do you think the problem might be?

I misspoke here: The current limit of two sources in parallel would be
2.828 amps, not the current into 50 ohms.

Alas, I don`t have Chipman`s book. Another source is Terman`s 1955 "Electronic and Radio Engineering". He solves the differential equations for a transmission line, starting on page 84 for solution of traveling wave problems.

Hi Jim,

I did some playing around comparing spline fits with manufacturers data points. The underlying problem is that the manufacturer might give a data point at say 50MHz where the skin effect appears well developed (the data point is a good fit to the simple loss model constructed with that data point and the ones at higher frequencies), and only one data point much lower (eg 5MHz) that is not a good fit to the model and suggests that

skin effect is not well developed at that frequency.

The lack of a good number of data points in the region where resistance is not proportional to f^0.5 prevents accurate modelling. The loss data doesn't provide enough information to infer the relative diameters of the high conductivity coating and the low conductivity core.

The approach I have taken with tllc is:
- explain the issue in the usage nots;
- carry into the summarised data, the lowest frequency on which the model is based so that it can be displayed and users aware when the model results are an extrapolation;
- the raw data has been analysed to find low frequency data points that are more than 10% different to forecast by the predicted loss model, and those points have been excised and the models recreated;

For example, the data for Belden 1189A (a CCS inner conductor) has had a 5MHz data point excised, and the lowest data point used is now 55MHz. The calculator results shows that frequency, and the user must make his own mind up about the applicability of an extrapolated result.

I use RG6 coax that has a hard drawn copper centre conductor, and tllc's results for Belden 1189A (an RG6 type) are probably quite reasonable at 3MHz, but the results would underestimate the loss in real Belden 1189A because of its use of CCS inner conductor.

An interesting question is ladder lines. Taking Wireman's products, 552 which uses a #16 19 strand copper clad steel conductor or unspecified coating thickness might well have higher loss than 551 which has a #18 30% single core copper clad steel conductor at sufficiently low frequency. The question is at what frequency does the effect of the thinner copper coating of the thicker conductor bundle manifest itself. I know that Wes measured these lines, and in the article I read he stated that the measurements were done between 50MHz and 150MHz which would probably not have shown the effects of the thin coating at low frequencies.

Some of the best reasons are empirical. Numerous studies have shown
that the clutter return from the sea surface is considerably higher in
horizontal polarization. I am on vacation, so I don't have my Skolnik
handy to say exactly how much. Anyway, this favors a vertical polarization.

Similarly, practical considerations make vertical polarization the best
for mobile applications. The 1/4 whip is the simplest antenna structure
on a mobile platform. While base stations could as easily use
horizontal or vertical, any mobile horizontal antenna will require extra
structure to implement.

In both of these applications there is nothing be gained by going to any
other polarization than vertical for these uses. In cases where
horizontal polarization has an advantage, there is no reason to go
partly vertical. So that is why the world end up either being vertical
or horizontal for the most part. Where it doesn't, polarization usually
doesn't matter or is less of a concern than other reasons (see inverted
vees and sloping dipoles).

3792. Constructive interference in radiowave propagation

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-06 21:37:21 UTC
From: MRW <mr.whatever@gmail.com>

Source record: 43458

In my physics book, it mentions constructive and destructive wave interference especially in reference to the the one-slit diffraction experiment. From reading about radiowave propagation, they also mention diffraction effects on radiowaves.

To me, it sounds like with constructive interference, the wave's amplitude will have the chance of increasing more than what the source actually outputted. But I wonder if this is helpful in terms of radio communication.

In reference to a single frequency transmitted, when I think about constructive interference and radiowave propagation, I keep picturing a delayed signal transmitted at time_0 and another signal transmitted at time_1 later with the same phase arriving at the receiver at the same time.

In terms of AM, I would think this would be problematic.

Any comments? Really, what I'm trying to understand here is: if constructive interference does any good in radiowave propagation. I was thinking that with an increase in amplitude the signal would be able to travel a little further, but the signal received may not be accurate in terms of the information it is conveying.

Thanks!

Belden and Commscope are the top names in CATV/Satellite cables and
compression connectors are now the standard for all satellite installs.
T&B Snap-N Seal is considered the best of the compression connectors.
The two big satellite companies not only spec compression connectors but
also solid copper center conductor RG-6 due to the lower DC resistance
for powering equipment down the cable. If you use say, Belden 7915A
cable and T&B SNS1P6U connectors, nobody can ever say you skimped.

> case, as a relative speed dependent on the medium.

As others have pointed out, it's risky to treat c as a variable or medium-dependent speed. That letter is nearly always used to designate the speed of light (or any EM plane wave) in a vacuum. Using that nearly-universal definition, the speed of an EM wave in any other medium is VF * c where VF is the "velocity factor". It's important to realize that while there's a single value for the speed of all EM waves in a vacuum (c), this isn't true in many other media. In many media, the speed of the wave depends on its frequency, a phenomenon called "dispersion". So in many media there's no universal EM velocity equivalent to c, but rather a frequency-dependent velocity factor.

In environments where the field is confined such as a waveguide, the velocity can also depend on the mode, that is the orientation of the fields. So there's not even a single value for each frequency. And this can be true even if the waveguide is filled with a vacuum.

Roy Lewallen, W7EL

the amplitude can be more in one direction than another, but the total power can not exceed the transmitter output of course. for each constructive interference peak there must be an area of destructive interference to make up for it.

>
> In reference to a single frequency transmitted, when I think about

> In terms of AM, I would think this would be problematic.

yep, that is what ghosts on tv signals are... if the delay is long with respect to the modulating signal you can get effects like that. the most common desirable uses are in antennas where there is a phase delay about equal to the spacing of the elements of the antenna which lets you create a stronger signal in one direction, and of course a weaker one in other directions, allowing you to put more of the transmitter power in the direction you want it to go. because the delays are small there is not the problem with ghosts.

yes, constructive interference is what antenna design is all about... destructive interference has its part also to help reject interference from undesired sources as well.

Jim Kelley wrote:
> There
> is nothing wrong with the proper use of superposition and interference.
> Given that, what do you think the problem might be?

Please don't tell me you don't understand constructive
interference.

Quoting "Principles of Optics", 4th edition, by Born
and Wolf, page 257:
****
Suppose now that two monochromatic waves E1 and E2
are superposed at some point P. The total electric
field at P is

E = E1 + E2 (6) so that

E^2 = E1^2 + E2^2 + 2*E1*E2 (7)
****
[Note from w5dxp: Each one of those terms in
equation (7) is proportional to power which is
proportional to intensity! The last term in the
equation is certainly proportional to interference.

Resuming the quote from Born and Wolf:
****
Hence the total intensity at P is

I = I1 + I2 + J12 (8) where

I1 = <E1^2> and I2 = <E2^2> (9a)

are the intensities of the two waves, and

J12 = 2<E1*E2> (9b) is the *interference term*."
****
As you know, the power associated with the wave is
proportional to E^2 so if E1 = E2, the power in
the superposed waves is four times the power in
a single wave. That's the nature of total constructive
interference as explained by Hecht in "Optics", 4th
edition, page 388.

Hint: When two identical EM waves are superposed
in phase in free space, the ratio of the E-field
to the B-field must remain equal to 377. The E-field
doubles and the B-field doubles so the (power) in the

wave quadruples to

Ptot = (E1+E2)x(B1+B2) = 4*E1xB1

Such is the nature of constructive interference. If
Keith can get two IC-706's to do that, I will believe
that superposition is valid for IC-706's.

Antenna gain over isotropic is an application of
constructive interference. The constructive
interference must be balanced by an equal amount
of destructive interference elsewhere to avoid
violating the conservation of energy principle.

If I remember correctly, at Texas A&M we used an
equation like:

c' = VF(c)

Writing c-prime like that told us that it wasn't
the speed of light in free space.

Prevents accurate modeling from measured data.. or, more accurately,
prevents you from validating your model with measured data.

I think you could develop the model from physics (which is how the
sqrt(f),f models were developed), and then determine the coefficients
for a particular type coax by measurement.

I would start by looking at Rac/Rdc for the center conductor for low
frequencies. Some reasonable assumptions are
a) dielectric loss is negligble
b) loss in the shield can be modeled by the infinite plane skin depth
formula.

References such as the ITT Reference Data For Radio Engineers have a
short table from which you can build a piecewise model. The analytic
model is a bit complex (hah.. as I recall, it involves Bessel functions
and elliptic integrals)

Stranded copperclad is a very tricky thing (much like measuring the RF resistance of braid) because you have both the skin effect in a single conductor issue and the proximity effect of adjacent conductors, and on top of that, the current flow among conductors (the inner conductors carry less current than the outer ones).. Much like trying to analyze Litz wire.

Maybe the thing to do is to actually measure some samples and bound the error.. (probably not worth going farther if the error is 0.1 dB in 1000 ft, for instance).

I'd start by just running the numbers for solid copper and see what the difference between the "thin walled tube model" (implied in the sqrt(f) term) and the actual "solid conductor with skin effect"

3800. Re: Convert reflection coefficient to Z

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-06 23:25:47 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <131dlo1oech4464@corp.supernews.com>
Source record: 43465

The loss of real coax often doesn't fit simplified models for at least the following reasons:

1. Plated or tinned center conductor, where plating or tinning is thinner than several skin depths at the lowest frequency of analysis.
2. Roughness of a stranded center conductor.
3. Roughness of a braided shield and the necessity for the current to migrate from wire bundle to wire bundle.
4. Shield thickness which is less than several skin depths at the lowest frequency of analysis.
5. Tinned shield.
6. Multiple shields.

Numbers 1, 4, and 5 can be calculated, but require modified Bessel functions and often some mathematical trickery to prevent truncation or overflow errors even with extended precision calculation. The remainder are often empirically determined, are complex functions of frequency, and vary from one cable type or manufacturer to another. All can be significant with typical cables at HF.

Roy -

The convenient thing about using medium dependent c in that equation is that we can use things such as index of refraction or velocity factor to convert from vacuum 'c' to 'c' in another medium. The fact that it makes the results of the calculation more accurate tends to mitigate any risk that might be encumbered when using it.

To require that only vacuum c be used in the equation to me seems overly authoritarian. I wonder how you feel about the speed of sound? :-)

Don't forget Times Fiber at the top right there with CommScope and Belden.
As far as compression fittings, Snap-N-Seal definitely is in the top group,
right along with PCT, Digicon, Gilbert, & PPC. The whole shebang started
with PPC.

Hello MRW,

As long as the constructive interference occurs over the full bandwidth of your signal, it helps you without the need for equalizing. Another way to see it is that if the delay of the (reflected, refracted, etc) signal is far below 0.25/(RF bandwidth) the signals will add constructively when the carriers are in phase at the point of interference (inclusive the side bands generated by the modulation).

This becomes more difficult (or impossible) for wide band signals. One can see that in the frequency response of the propagation path. Imagine when you transmit a signal with uniform power distribution (brick wall spectrum). Receive it with an antenna and examine the signal wit a spectrum analyzer. When the spectrum is flat (as the original signal), then you will not have problems demodulating the signal. However when you see many dips and peaks in the spectrum, the information on the signal will be distorted. You will need an equalizer (inverse FFT, deconvolution) to remove the distortion.

Another test is to transmit a very narrow pulse (amplitude modulated). Receive the signal en show the demodulated version on an oscilloscope. When the demodulated pulse has been stretched, you have distortion in the modulation.

The effect of distortion in mobile systems due to multiple waves arriving at an antenna, results in so called "frequency selective fading".

About analog AM, the BW of the signal is about 8 kHz, As long as the delay of reflected/refracted waves is less then 30us (that is 9 km in distance), you will not have problems with signal distortion (valid for surface wave propagation). With propagation via the ionosphere, the situation is different; there the path length of several waves can be so different, that for example waves with frequency 13.720 MHz interfere constructively, but with frequency 13.722 MHz they interfere destructively.

So when you don't want distortion because of destructive and constructive interfering wave fronts, you should have a narrow bandwidth (that is low bitrate). This is done in multi carrier modulation (like COFDM [TDAB, DVBT]). Many or some carriers will suffer from destructive interference, but also many will be subjected to constructive interference. By adding sufficient redundancy, the data stream from the sub carriers having good signal strength can be demodulated to the original data stream.

Relative high baud rate systems (like the GSM system) use equalizers/ echo cancellators to mitigate the effect of multi-path reflections.

Best Regards,

Wim

With an extended ascii chart (giving the decimal value of the character) and the alt-key combined with the number pad, it is possible to enter extended ascii. However, not all news servers will honor all extended ascii characters and not all news readers will represent them correctly (plus, you probably have to set the news reader to allow them in it's settings.)

Hold down the alt key while entering 2-5-3 (253) from the numeric keypad, release the alt key and "²" is presented--so can all extended ascii be created in notepad, dos edit, etc. ...

Jim, it is obvious that you do not understand
constructive interference between coherent EM waves.

The stuff I quoted from Born and Wolf agrees with Hecht
and contradicts what you have said. In particular, equation
(7) on page 257 contradicts your earlier posting. Given
that power is proportional to E^2, please explain how the
following equation is possible in 377 ohm space in light
of your earlier posting.

E^2 = E1^2 + E2^2 + 2E1*E2

From that equation, Born and Wolf develop the interference
term which they call J12, same as Hecht's I12, same as
Dr. Best's 2*SQRT(P1*P2).

This is exactly what Hecht described in "Optics". Seems
that you don't realize that the square of the sum is
more than the sum of the squares when constructive
interference between two coherent EM waves occurs.

Two identical EM waves in free space must maintain the
377 ohm free space ratio. Therefore, if the E-field doubles,
the B-field must also double, contrary to your earlier posting
that said that voltage and current could not double
simultaneously but that is exactly what happens in a fixed
Z0 environment like free space or a transmission line.

I explained this to Dr. Best way back in 2001. That you
don't yet understand it is the cause of our many arguments.

>out of the glass separated in time slightly, implying that they took
>different times to get through the glass, and were therefore not even
>travelling through the glass at the same velocity; I notice no such
>separation for the light passing through the vacuum.

Same as what? Different wavelengths respond to different inertial
frames of reference, a prism demonstrates this quite dramatically.
This happens quite commonly for wideband transmissions through fiber
optics. The solution has been to send them as Soliton waves. Another
solution is to employ micro channels.

>Further, I
>notice that light from a distant star has apparently the same set of

>inertial frame of reference...

There are a lot of "same"s here and some are being shown to be
different, and others same. I'm wondering what the point is that I'm
way off from.

Cecil - I have had Born and Wolf on my shelf for years. I use it regularly. I understand interference. It's not difficult. I work with it on a regular basis in fact - both optically, and at RF.

> In particular, equation
> (7) on page 257 contradicts your earlier posting. Given

Power doesn't interfere. It doesn't even propagate, Cecil. (You might note the distinct absence of any descriptions of how power propagates in the physics texts. Hopefully you'll also note the absence of any discussion of how power constructively and destructively interferes in Born and Wolf.) And as the above equation points out quite plainly, electric fields interfere. Electric fields do propagate, along with their counterpart: magnetic fields.

> From that equation, Born and Wolf develop the interference
> term which they call J12, same as Hecht's I12, same as

I think you'll find the equations to be largely the same in most optics texts, Cecil. No need to point that out.

Jim Lux <james.p.lux@jpl.nasa.gov> wrote in
news:ev6k4qbos1@nntp1.jpl.nasa.gov:

Jim,

Comments noted.

My objective isn't so much trying to build a better loss model, but rather to use a simple loss model and build the coefficients from manufacturer's published data and make that available in the calculator.

Although I calculate the correlation coefficient when do the regressions on the manufacturers freq/loss tables, and had not used models with poor r^2, I hadn't explored the lower frequency data points for fit. I did just that a day or so ago, and interestingly the cases where low frequency points were not a good fit were all non-homogenous centre conductors.

I had previously explored thin homogenous centre conductors, and they should not be an issue for practical cables down to 0.1MHz.

I am also not obsessing about accuracy, because real cables have tolerances that set a limit to necessary accuracy.

So, to try and persevere with the simple model, I have excluded data points that appear to be a result of departure from the simple model due to composite conductor effects, and show the lower frequency that bounds extrapolated / interpolated results. Extrapolated results are always a risk, the user must make their own judgements about the applicability.

I noted Roy's comments on braids and composite conductor issues, and I thank him for his response. I may include some similar explanation in the calculator's usage notes.

It also occurs to me that some cable construction intended for 500MHz and above use a plastic film with a very thin metallic coating, and I wonder about its performance at low frequencies. Perhaps yet another departure from a simple loss model.

As noted above, the largest departures at low HF frequenciesfrom the simple loss model were all cables with steel cored inner conductors. There is a salutory lesson that when buying RG59 or RG6 for HF use, those cables with 100% copper inner conductors are likely to be better at the low end of HF. The same may apply for use of such cables for baseband applications like video.

What, the speed of sound in a vacuum? I'm afraid you'll have to ask Cecil or Art about that -- I'm not qualified to comment.

I'm not trying to be authoritarian about the use of "c", just reporting what I find in my textbooks. Grabbing just one for example, Kraus' _Electromagnetics_, on p. 352 I find that he uses v as the phase velocity, and says, "For free space (vacuum) the velocity is a well-known constant (usually designated by c and usually called the velocity of light)." and shows an equation for c. Then he gives an equation for the "relative phase velocity" p, as v/c.

In the back of R.K. Moore's _Traveling-wave Engineering_, c is listed as "Velocity of light in vacuum". He uses v-sub-p for phase velocity.

A number of authors avoid using c altogether, but those who do seem to universally use it to mean the speed of light in a vacuum. What texts do you have where it's used to mean the phase velocity in a medium other than air?

Of course, you can always go ahead and interpret c any way you want, even if it isn't what the author intended. Then you can progress from there to any number of bizarre conclusions. They'd fit right in with the ones being "debated" over and over on this newsgroup.

Exactly as I said in my energy analysis article:
"The term "power flow" has been avoided in favor of "energy flow". Power is a measure of that energy flow per unit time through a plane. Likewise, the EM fields in the waves do the interfering. Powers, treated as scalars, are incapable of interference."

So please cease and desist with the straw man already.
You are simply quoting my article back to me.

And you are missing the point. When you said that voltage and current cannot both double during superposition you were 100% wrong. That error of yours is what our years long argument has been about. Keith is apparently making the same error as you.

Consider two identical EM waves superposing in free space. Contrary to what you asserted in your previous posting, the E-field doubles in magnitude AND the B-field doubles in magnitude. The result is a quadrupling of the power contained in the superposed wave compared to the power contained in each original wave.

Unfortunately, manufacturer's published loss data are often quite different than actual cable loss. Belden RG cable I measured long ago was routinely considerably better than the spec -- apparently the spec was dictated by the MIL SPEC, and the cable was manufactured to never exceed it. More recently, I've found that in trying to convince rather naive amateurs to purchase their cable, some manufacturers are claiming considerably lower loss than the cable actually has. So the bottom line is that manufacturer's published data are just so many numbers, and don't necessarily have any direct relationship to any real cable.

Careful scrutiny of real cable will also reveal that the characteristic impedance varies quite a bit, and the velocity factor of foamed dielectric cable is even more variable.

The speed of sound in a vacuum is measured using the sound of one hand clapping.

I understand. One of the cable types that I tried to fit to the loss
model was Davis Bury Flex, and it had the worst regression errors of all
of the 90 line types that I modelled. Of course, some manufacturers data
is an extremely good fit, and I suspect that is a result of fitting their
own measurement data to the same model, then publishing points from the
modelled performance.

>

Agreed... but you have to start somewhere with design, and the
manufacturer's data isn't such a bad place to start. But, I hear your
point that obsessing about model accuracy isn't wise.

Ah, yes, that stuff. It's easy to make it fit a model at about 200 MHz and above -- just flex it a bit until the loss matches your model. At 400 MHz, you'll have even more variation to work with.

This is what I've been trying to persuade the 'anti's' that whenthe radiation fields from two vertical dipoles
superpose at some point in space, where their magnitudes are equal and are 180ï¿½ out of phase, the wave
cancellation resulting from destructive interference produces a null in a predetermined direction, and thus
prevents those fields from propagating any further in that direction. At the precise instant the null is
produced, the constructive interference following the principle of energy conservation yields an increase in
the field strength in directions away from the null direction. This explains the concept of antenna-pattern
modification, and contradicts the notion that the two fields just plow through each other with no effect on
either.

Keep in mind that the two fields are coherent because they were developed simultaneously from the same source.
It is true, however, that two non-coherent fields from two different sources would just plow through each
other with no effect on either.

At 6m in height, it is nearly long enough to have reasonably good
performance at 7MHz. You would want to ensure reliable, noise free
connection between the sections and devise a suitable insulated mounting.
You could brick a small pedestal at the base to house an auto tuner, and
there you go, a multiband vertical for 40m to 10m.

Fig 2 at http://www.vk1od.net/multibandunloadedvertical/FP-40C.htm might
give some insight into expected performance at 7Mhz.

Walt, this seems inconsistent with the approach that I believe you seem
to use in analysing waves in transmission lines where you seem to want to
not only deal with the forward and reverse waves separately (ie to not
collapse them to a resultant V/I ratio at a point), but to deal with
multiply reflected waves travelling in the forward and reverse direction
(which is only necessary in the transient state).

Owen

3828. RG-6 Coaxial Cable for Ham use

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-07 05:31:53 UTC
From: Nod Dloyd <anon@anon>
Message-ID: <r3vt5.kv4.19.1@news.alt.net>
Source record: 43494
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.misc,rec.radio.amateur.policy

I've recently read comments that several Hams have been using the RG-6 coaxial cable instead of the standard RG-8 or other commonly accepted cables such as RG-58.
One said that he buys this RG-6 at one of the home warehouse stores and buys it in 500 foot spools. He said it is far less expensive than the commonly accepted cables we purchase from various Ham outlets.
Yes, it is 75 Ohm cable, but the users of same claim that it works quite well and can withstand higher voltages than advertised and more than one user claimed that they could run 1,500 watts through the cable with no apparent deterioration.

If this is so, then I missed this open *secret*. Any input would be welcome...especially the experiences of you who use it. I just happen to have a spool of this cable in my garage that I purchased at an estate auction some years ago and if it works as said, then I will cancel my order with The Wireman.

Thanks in advance for your comments.

Hi Walt,

Well, having broached the topic, it appears time to plunge in once
again.

Several but closely related questions:
What separates "effect" from "no effect?" (They are, afterall, a
rather strict binary outcome.)

Does the binary transition from a one micro-degree longer
cycle (non-coherent) to 0 (coherence) same length cycle really
plunge us into a new physical reality of waves colliding with
rebounds and caroms where formerly there was absolutely no
interaction before?

Can one not change the location of the nulls by changing
the phase relationship of the two sources?

If so, it would seem to me that two non-coherent fields are
simply fields without a constant phase relationship and as
such, the nulls are constantly moving; still present, but
not stationary.

The 75 ohm part should not (in general) be a problem. You could always use a tuner if there is an issue. However, here are the things you should check.

1. Loss per hundred feet (see the ARRL antenna book) for the frequencies you are going to use. A long run at VHF/UHF might be an issue.
2. Check its rated power versus the power you plan to run. If it's TV cable (which it probably is), I doubt that it is rated very high. I've never checked so can't really say. However, just because some people get away with running 1500 watts through it doesn't mean you should. The deterioration may not be immediately evident. It may simply shorten its life and you'ld be replacing it more often.
3. Check to see it's UV rating. Outdoor environments are hard enough on coax. Some are designed for indoor use and others for outdoor use. If this is the indoor kind, it will deteriorate much faster if used outdoors and you will be replacing it more often.

The antenna system (and this includes the coax) is perhaps the most important part of your setup. It's best to do it right so check on the items I mention. Don't be like the classic case of the fisherman who buys a $500 rod but puts on a $5 reel and nickel fishing line and then is always cussing that the line snarls and the reel jams.

In other words don't be penny wise and pound foolish. Make sure that the coax is suitable for the application.

I haven't bought coax in a long time (probably due to replace the old by now) but I believe his is rated for outdoor environments and UV exposure.

Andy writes:
Correct. One example is a television signal that is received from two
sources : 1) a direct line to the transmitting tower and 2) a reflection
from an airplane flying .

Even tho both received signals are generated from the same source,
the reflected signal will be changing in amplitude and phase as the reflector,
the airplane, moves along it's flight path.

The two signals combine at the receiving antenna and the
resultant signal into the receiver will rise and fall, depending on
the resultant amplitude and phase. The maximum can be several
db above the direct signal and the null can be many many db
BELOW the direct signal.

Hence, you see the image come and go for several seconds on
your screen. After several seconds the plane will have moved to a position
such that the reflection doesn't hit your antenna anymore, and the
problem goes away. We've all seen this. In fact, 70 years ago, this
effect (on radio signals) was what inspired the development of
radar.....

Of course, you are being facetious but the answer is simple.
If the two signals are mutually incoherent, they don't
interfere. Permanent wave cancellation is impossible
between two waves that are not coherent. Hecht in "Optics"
devotes an entire chapter to the "Basics of Coherence Theory".
So do Born and Wolf in "Principles of Optics". Here is what
Walt was obviously saying except in Born and Wolf's words:

"If the two beams originate in the same source, the fluctuations
in the two beams are in general correlated, and the beams are
said to be completely or partially *coherent* depending on
whether the correlation is complete or partial. In beams from
different sources, the fluctuations are completely uncorrelated,
and the beams are said to be mutually *incoherent*. When such
beams from different sources are superposed, no interference is
observed under ordinary experimental conditions, the total intensity
being everywhere the sum of the intensities of the individual beams."

In case you missed it, that says *NO INTERFERENCE* between mutually
incoherent waves. Seems reasonable to say that "no interference"
means the same thing as "no effect".

If the waves are mutually incoherent, there is
NO interference which means no effect on each other.
Constructive and destructive interference is
impossible between two mutually incoherent waves
(under ordinary experimental conditions).

It is a rather strict binary outcome when we are
discussing coherent vs mutually incoherent waves
as Walt obviously was. The gray area in between
to which you are alluding is called "partial
coherence". It is the region between "coherent"
and "mutually incoherent" which makes it three-state,
not binary, much like a logic 0 vs a logic 1 with
an in between region.

We generally would not have to worry about "partial
coherence" in a transmission line but if you want to
nit-pick that subject on rraa, be our guest.

The 75 ohm cable is fine for usage. There are several minor problems to
watch out for. The major one is most of it is aluminum shielding and can
not be soldered to. The center conductor is often copper coated steel which
is another mechanical problem.
I am not sure about the power rating for the rg-6 but should be fine for the
100 watt rigs. The swr meters may not act correctly with the 77 ohm
cable, but you can still adjust for minimum swr.

3839. Interference

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-07 14:39:37 UTC

Seems that some people are confused about EM wave interference. Here's a quote from "Optics", by Hecht:

"Optical interference corresponds to the interaction of two or more lightwaves yielding a resultant irradiance that deviates from the sum of the component irradiances."

The units of irradiance are joules/sec/unit-area which are the same units as the Poynting (power flow) vector. So putting Hecht's interference statement into words familiar to RF engineers, we can say:

RF wave interference corresponds to the interaction of two or more RF waves yielding a total Poynting vector that deviates from the sum of the component Poynting vectors.

It follows that if the total Poynting vector does not deviate from the sum of the component Poynting vectors, then there is no interference, by definition.

Here's the kicker to this discussion of interference. Assuming the following wave components are moving in the same path in the same direction:

1. Superposing two mutually incoherent EM waves of equal magnitudes results in a maximum possible intensity that is the sum of the maximum intensities of the two waves, i.e. two times the maximum intensity of a single wave.

2. Superposing two coherent EM waves of equal magnitudes results in a maximum possible intensity that is greater than the sum of the maximum intensities of the two waves, i.e. four times the maximum intensity of a single wave.

In a nutshell, that is the difference between waves that interfere and waves that do not interfere. Light waves that interfere can be twice as bright as light waves that do not interfere. The constructive interference term can double the intensity of the sum of the intensities of the component waves. The extra energy is supplied from areas of destructive interference (or by a local source).

>Owen
>

Owen, it appears that you've misinterpreted my approach. In developing a condition for impedance matching,
such as adding a series or shunt stub at the proper place on a transmission line, the object has always been
to generate a new reflection at the stub point of the opposite phase to that appearing on the line at the stub
point. Thus when the stub reflection and the load reflection superpose at the stub point, the resulting
reflection coefficients of voltage and current form either a virtual open circuit or a virtual short circuit.
These conditions are produced because when the load impedance is greater than Zo, the resultant reflection
coefficient angles at the stub point are 0ï¿½ for voltage and 180ï¿½ for current, establishing a virtual open
circuit at the stub point to rearward traveling waves. When the load impedance is less than Zo, the resultant
reflection coefficient angles are 180ï¿½ for voltage and 0ï¿½ for current, establishing a virtual short circuit at
the stub point for rearward traveling waves.

If you want more details on how the resultant reflection coefficients are developed I'll be glad to furnish
it.

I started using Times when I started in cable in '85. Have used the other 2 aforementioned brands, but still spec Times for our systems.

That tool, as well as three of the ones listed here http://www.cencom94.com/gpage.html2.html (CT-FBR, PCT-DRS-CT, & PCT-DRS-CT-AS), Cable Pro's LCCT-1, and many others fit those fittings. Only sort of exception in that group of fittings is PPC. They originally started out with the EX Series, which is about 19mm in length. Then others started making compression connectors that were 21mm in length, which is what the majority of them are. A few years ago, AT&T Broadband pushed PPC into making a 21mm fitting, which they labeled EXXL. PCT also has a Universal connector (TRS Series) which is a different length.

Cecil,

In my line of work I get to deal with partial coherence every day. The fading of TV signals due to multipath reflections from airplanes is not at all what B&W are describing.

By "NO interference" did you mean "sufficiently close to zero
that it can be ignored for engineering purposes", or "exactly
zero"?

If the former, a bit more precision in your writing would be
valuable. The use of CAPITALs certainly suggests the latter.

If the latter, how incoherent do the waves have to be before
the interference suddenly drops to ZERO.

If *mutually incoherent*, then exactly zero, according to
Born and Wolf. "Mutually incoherent" excludes any possibility
of coherency.

> If the former, a bit more precision in your writing would be
> valuable. The use of CAPITALs certainly suggests the latter.

Note that I didn't say anything about partially coherent
waves or partially incoherent waves. Whether two waves are
coherent or mutually incoherent is indeed a binary situation.
Any middle ground is thus excluded from my statements.

> If the latter, how incoherent do the waves have to be before
> the interference suddenly drops to ZERO.

I believe mutually incoherent means the same thing as
perfectly incoherent.

Walt,

Your observation is "correct" only in the case that most people consider
for practical reasons. The calculation showing the null behavior is
almost invariably performed at infinite distant from the sources, i.e.,
far field condition. The path from each source to the observation point

is considered to be exactly parallel.

As you know, there are usually three or more linear dimensions that enter into radiation calculations. In the case of two sources there are four:

Wavelength
Size of each source
Distance between sources
Distance to the observation point

In the typical "null" presentation, such as that shown in the ARRL publications, the distance to the observation point in always large.

Lets take another case, however. Suppose the distance between the sources is some what larger than the wavelength. Make it large enough so there is a region between the sources that would be considered far field from each of the sources. Now calculate the phase differences along some direction from the center point between the sources that eventually points to a null region in the infinite distance. Don't pick an obviously symmetric direction, such as broadside or end-fire, as that would be a special case.

What you will find is that when looking at the phase difference along the ultimate null direction is that there is no such null much closer to the sources. The paths from the individual sources are not parallel in this case. The null "line" is actually a curve. The waves pass right through each other in the closer region. The "passing waves" then go on to form nulls in the infinite distance. The nulls in the closer region are not in the same directions as the nulls in the far field.

Again, the ground rules:

Totally coherent, monochromatic sources
Fixed phase difference
Far field conditions for each source

There are no "tricks" here; this is just a matter of simple geometry. However, it shows that the null you believe demonstrates some permanent interaction and annihilation of EM waves is simply a special case.

In classical, non-cosmic, non-relativistic conditions EM waves do not interact in free space. This condition is so widely understood in the scientific world that it becomes a prime candidate for argument on RRAA.

Hi Keith,

Your question of parsing "NO" reveals one of those binary shifts in an otherwise analog word that has me puzzled too. There is also the amusing "mutually incoherent" redundancy. Aside from these sophisms, there is a conceptual, quixotic tilting at windmills in the phrase:
>>no effect on each other
as if waves ever affected each other (irrespective of coherence - mutuality notwithstanding).

If the past is an indicator of future activity, this topic is about to split into other discussion with a desperate attempt to appear to be answering for these strange theses.

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not
actually annihilated, ... All of the photon energy present in
these waves must somehow be recovered or redistributed in a new
direction, according to the law of energy conservation ... Instead,
upon meeting, the photons are redistributed to regions that permit
constructive interference, so the effect should be considered as a
redistribution of light waves and photon energy rather than the
spontaneous construction or destruction of light."

> In classical, non-cosmic, non-relativistic conditions EM waves do not
> interact in free space. This condition is so widely understood in the
> scientific world that it becomes a prime candidate for argument on RRAA.

Florida State University seems to disagree. "Upon meeting"
in free space, the interfering photons are "redistributed".
RF waves are EM waves. Just because we cannot see them is
no reason to assert that they act differently from EM waves
that we can see.

Hecht, in "Optics", says about interference:

"At various points in space, the resultant irradiance can
be greater, less than, or equal to I1 + I2 depending on
the value of I12 ..." I12 is previously defined as the
interference term. Hecht's "various points in space"
seem to contradict your assertion that waves "do not
interact in free space".

From Born and Wolf: "Thus if light from a source is divided
by suitable apparatus into two beams which are then superposed,
the intensity in the region of superposition is found to vary
from point to point between maxima which exceed the sum of the
intensities in the beams, and minima which may be zero."

If "region of superposition" is not referring to the free
space point of interference, to what is it referring?

When one can see with one's own eyes the interaction of
two light beams in free space, how can you possibly deny

the existence of that interaction?

Not my words, Richard - they are straight from Born and Wolf.
Do you really think Born and Wolf would engage in "redundancy"
if it were meaningless. Suggest that you learn the difference
between mutually inclusive and mutually exclusive.

> Aside from these sophisms,
> there is a conceptual, quixotic tilting at windmills in the phrase:

Coherent waves can and do affect each other. It's called
interference where the sum of the intensities is different
from the intensity of the sums. Incidentally, the intensity
of the sums is the mistake you made when you calculated
the reflection from non-reflective glass to be brighter
than the surface of the sun.

Sorry, that should be the "sum of the intensities".
The intensity of the sums is the way to correctly
calculate total intensity. The sum of the intensities
yields an incorrect answer as Richard earlier discovered
with his "reflections brighter than the surface of the
sun" calculation.

Gene, at this point I can't disagree with you. However, in your next to the last paragraph in your post above,
if I interpret you correctly, you are saying that all directional arrays, such as are used in AM broadcasting,
are considered 'special' cases. Is that what you mean't to infer?

Poor language is not excused by example. Being meaningless I leave to
your interpretations, however.

This only reveal two incidents that are amusements.

Are you sleeping with Born and Wolf now?

You seem to have missed (Born and Wolf)'s point.
Between coherent and mutually incoherent is
a span of signals which they call partially
incoherent. There are degrees of incoherency
as can be seen from your postings. :-)

I think what Walt is trying to do is explain that there is
no interference at power up. As the reflections build up,
the interference builds up, until there is total
destructive interference toward the source during steady-
state and total constructive interference toward the load.
Without interference, a Z0-match would not be possible.

The principle of superposition gives us permission to
analyze the forward and reverse separately and collapse
them to a resultant V/I ratio later. If one wants
to use the simplified mashed-potatoes approach, that is
OK since the results are the same in either case.

I would not run it up the tower, or anywhere else that is hard to get at.
Without spending an arm and a leg, use crimp on connectors. I have some
PL259 type crimp ons (Digikey), and they work fine, even at a KW+. I did
solder the center conductor on the LMR240 (same diameter as RG6). The center
conductor might be way too small for the hole in the connector; in that case
stuff some pieces of wire in next to the center conductor so you are not
connected through solder only.

Of the few samples that I looked at, the black RG6 was outdoor rated, the white jacketed was not. Kind of makes sense. Didn't see any power ratings at the Belden site, but I seem to recall seeing ratings in the few hundred W range.

Hi Walt,

I read the above, and I think I can see what you are getting at, however I think it is flawed.

If you were to try to extend this method to explain the common two stub tuner (where the length of the stubs is adjustable and the distance between them is fixed), you will have to deal with a situation where the load end stub junction does not present the "virtual o/c or s/c" you describe, your "total re-reflector concept" and you come to need to calculate the situation on the source side of the load end stub (possibly by conventional methods?).

Walk your explanation around a Smith chart, and explain why, if the principles on which your explanation are based are correct, why energy fills a 3/4 wave hi Q coaxial resonator rather than being blocked by the virtual s/c or o/c at the first voltage minimum or current minimum.

Someone else persuing the theme that reflected waves always travel all the way back to the source, seems to come to a position that some kinds of matching produce a complementary reflected wave, and that really there are two (or more) reflected waves, its just that they have zero net energy. Some of us would accept that if the resultant is zero, there is no wave. Otherwise, you would see a multitude of net-zero waves all around us to complicate every analysis.

These "new" and alternative explanations are questionable and don't seem better than the conventional explanations of a transmission line that are set out in just about any reputable transmission lines text. What advantages do these explanation have, who are they targeted at? Is the "total re-reflector" concept to appeal to a dumbed down audience who can get their mind around a bunch of words that describe specific situations

in a simple and appealing way, but an incorrect explanation nonetheless?

I think it is a real challenge to teach people a simple explanation of what happens without telling them convenient lies that have to be unlearned to develop further. The "reflected wave is (always) dissipated in the PA as heat" is an example of one of those convenient lies.

Owen

A term from "Principles of Optics", by Born and Wolf. It was
apparently
replaced by "irradiance" in "Optics", by Hecht. Intensity, irradiance,
and
Poynting vectors are all power densities, joules/sec/unit-area.

Are you sure that's not a straw man? Who, exactly, has voiced that lie
(besides Keith and his ten cent resistor?) :-)

> Walt, W2DU

Hi Walt,

Yes, those are special cases, but those special cases are the only ones
that most people care about.

What I was trying to say might be better illustrated by the following:

Two coherent laser beams from the same source can be arranged by
suitable mirrors to intersect at some angle. There will most definitely
be interference in the region of intersection, but the beams will
continue through unchanged. If one measured a beam somewhere downstream
from the intersection region it would not be possible to determine that
it had crossed another beam earlier.

The beams "interfere" but they do not "interact". I know this sounds
goofy, and it is critical to keep the definitions straight. When I say
the beams do not interact I mean that they do not cause any changes in
the other beam. The fact that the beams interfere means that the sum of
the fields shows the characteristic constructive and destructive
behavior. It does not mean that the waves are henceforth changed.

OK, so how does this square with the observation that there are nulls in
patterns from two or more RF sources? It is actually very
straightforward. In the far field the waves from the separate sources
are virtually parallel. Just like Timex, they interfere and they keep on
interfering. They never really pass beyond the intersection region.

I know it seems like a subtle, or even meaningless, distinction. Do the waves interfere forever or do they actually annihilate each other? For many purposes it does not matter. However, the non-interaction of waves in free space is pretty basic to all of EM analysis.
